$$B_1 = f_0 + f_{1 \rightarrow a} + nRT_1 \left[ \left( \frac{P_a}{P_1} \right) - 1 \right] \quad (23-84)$$

The energy partition between blast wave energy and fragment kinetic energy is as described in paragraph 1.

**Vessels Completely Filled with an Inert High-Pressure Liquid\*** A typical example is the pressure testing of vessels with water. The energy available to cause damage is the sum of the liquid compression energy and the strain energy in the vessel shell. The sudden release of this energy on vessel failure generally creates flying fragments but rarely any significant blast effects.

The fluid compression energy up to about 150 MN/m<sup>2</sup> (22,000 psig) can be estimated from  $U_f = \frac{1}{2}\beta_f P^2 V_L$ , where  $\beta_f$  is the liquid bulk compressibility,  $P$  is the liquid pressure, and  $V_L$  is the liquid volume. At higher pressure, this simple equation becomes too conservative and more complex methods of calculating the fluid compression energy are required. The elastic strain energy for cylindrical vessels, ignoring end closures, can be estimated from:

$$U_m = -\frac{P^2 V_L}{2E(k^2 - 1)} [3(1 - 2\nu) + 2k^2(1 + \nu)] \quad (23-85)$$

where  $P$  = pressure of liquid  
 $V_L$  = volume of liquid  
 $E_y$  = Young's modulus of elasticity  
 $\nu$  = Poisson's ratio

Energy available  $U = U_f + U_m$ .

Only a small fraction of  $U$  is available to provide kinetic energy to the fragments. There are few data available, but in five incidents analyzed by High (unpublished data), no fraction was greater than 0.15. The fragment initial velocity can be assessed from  $0.15 U = \frac{1}{2} M V_f^2$ .

**Distance Traveled by Fragments** There is no method available to estimate the distance traveled by an irregularly shaped, possibly tumbling, subsonic fragment projected at an unknown angle. A conservative approach is to assume that all the fragments are projected at an angle of 45° to the horizontal and to ignore the aerodynamic effects of drag and/or lift. The range  $R_g$  is then given by  $R_g = V_f^2/g$ , where  $g$  = gravitational acceleration.

This is too conservative to provide anything more than an upper bound. Some limited guidance is given by Scilly and Crowther ("Methodology for Predicting Domino Effects from Pressure Vessel Fragmentation," *Proc. Hazards Ident. and Risk Anal., Human Factors and Human Reliability in Process Safety*, Orlando, Fla., 15 Jan 1992, p. 5, sponsored by AIChE and HSE), where the range, for vessels with walls less than 20 mm (0.79 in), is  $2.8 P_b$ , with the range in meters and  $P_b$  as the vessel burst pressure in bars. Other sources are Baker (*Explosion Hazards and Evaluation*, Elsevier, 1983, p. 492) and Chemical

\*An excellent review of the necessary precautions to be taken is given by Saville, "Pressure Test Safety," HSE Contract Research Report 168/1998, HMSO, U.K., 1998.

Propulsion Information Agency (*Hazards of Chemical Rockets and Propellants Handbook*, vol. 1, NTIS, Virginia, May 1972, pp. 2-56, 2-60).

**Fragment Striking Velocity** It is generally impossible to assess the fragment velocity, trajectory, angle of incidence, and fragment attitude at the moment of striking a target; consequently, the conservative view is taken that the fragment strikes the target at right angles, in the attitude to give the greatest penetration, with a velocity equal to the initial velocity.

**Damage Potential of Fragments** In designing protection for fragment impact, there are two failure modes to be considered: local response and overall response. Local response includes penetration/perforation in the region of the impact. Overall response includes the bending and shear stresses in the total target element; i.e., will the whole target element fail regardless of whether the element is penetrated or perforated?

**Local Failure** The penetration or perforation of most industrial targets cannot be assessed using theoretical analysis methods, and recourse is made to using one of the many empirical equations. In using the equations, it is essential that the parameters of the empirical equation embrace the conditions of the actual fragment.

The penetrability of a fragment depends on its *kinetic energy density* (KED), given by

$$KED = \frac{1}{2} \frac{MV_f^2}{A} \tag{23-86}$$

where *A* is the fragment cross-sectional area. The KED is a useful comparative measure of a fragment's penetrability when comparing like with like. Several equations are given in the following sections.

**Ballistics Research Laboratory (BRL) Equation for Steel Targets**

$$E_p = 1.4 \times 10^9 (dt)^{1.5} \tag{23-87}$$

where *d* is the fragment diameter, *t* is the steel target plate thickness, and *E<sub>p</sub>* is the critical perforation energy in SI units (kg, m, m/s, J), when applied to fragments between 1 kg and 19.8 kg, impacting targets 1 mm to 25 mm (1 in) thick plate with velocities from 10 m/s to 100 m/s. Neilson (*Procedures for the Design of Impact Protection of Off-shore Risers and ESVs*, U.K. AEA [ed.], 1990) found a large scatter in the results, but most were within ±30 percent.

**Stanford Research Institute (SRI) Equation for Steel Targets**

$$E = \frac{dut^2}{10.3} \left( 42.7 + \frac{w}{t} \right) \tag{23-88}$$

where *w* is the unsupported span of the target plate (m) and *u* the ultimate tensile strength of the target steel (N/m<sup>2</sup>). The parameters for this equation are given by Brown ("Energy Release Protection for Pressurized Systems," part II, "Review of Studies into Impact/Terminal Ballistics," *Applied Mechanics Review*, vol. 39, no. 2, 1986, pp. 177-201) as 0.05 ≤ *d* ≤ 0.25m, 414 ≤ *u* ≤ 482 MN/m<sup>2</sup> for a fragment mass between 4.5 and 50 kg.

**Overall Response** The transition from local to overall response is difficult to define. High-velocity impact implies that the boundary conditions of the target have little influence on the local response (excluding reflected shock waves). If the fragment is small relative to the target, local response will dominate, but fragments that are of the same order of size as the target will produce an overall response. It is often necessary to consider both overall and local response. Low values of KED are associated with overall response. Design methods for dynamically applied loads are given by Newark ("An Engineering Approach to Blast Resistant Design," ASCE New York, 1953), Baker (see General References), or ASCE (*Manual and Reports on Engineering Practice*, no. 58, 1980).

**Response to Blast Waves** The effect of blast waves upon equipment and people is difficult to assess because there is no single blast wave parameter which can fully describe the damage potential of the blast. Some targets respond more strongly to the peak incident overpressure and others to the impulse ( $\int p dt$ ) of the blast. The blast parameters are usually based on the conservative assumption that the

**TABLE 23-25 Damage Effects**

| Incident, psi | Pressure, kPa | Damage effects   |
|---------------|---------------|--|
| 10            | 70            | Damage to most refineries would be severe, although some pumps, compressors, and heat exchangers could be salvaged. All conventional brick buildings would be totally destroyed. Rail wagons (rail cars) overturned. Storage tanks ruptured. Fatalities certain. |
| 5.0           | 34            | Brick buildings severely damaged, 75% external wall collapse. Fired heaters badly damaged. Storage tanks leak from base. Threshold for eardrum damage to people. Domino or knock-on radius. Pipe bridges may move.   |
| 2.0           | 14            | Doors and windows removed. Some frame distortion to steel frame buildings and cladding removed. Some electrical/instrument cables broken.*   |
| 1.0           | 7             | Lethal glass fragments. Limit for public housing, schools, etc.  |
| 0.3           | 2             | About 50% domestic glass broken.   |

\*1% probability electrical cables broken at 2.0 psi inc. 99% probability electrical cables broken at 3.6 psi inc.

blast strikes the target normal to its surface, so that normal reflection parameters are used.

The pressure exerted by the blast wave on the target depends upon the orientation of the target. If the target surface faces the blast, then the target will experience the reflected or face-on blast pressure *P<sub>r</sub>*, but if the target surface is side-on to the blast, then the target will experience the incident or side-on blast pressure *P<sub>inc</sub>*. The reflected blast pressure is never less than double the incident pressure and can, for ideal gases, be as high as eight times the incident pressure. For most industrial targets where the incident pressure is less than about 17 kN/m<sup>2</sup> (25 psi), the reflected pressure is not more than 2.5 times the incident pressure.

**Response of Equipment** The response of equipment to blast is usually a combination of two effects: one is the displacement of the equipment as a single entity and the other is the failure of the equipment itself. The displacement of the equipment is an important consideration for small, unsecured items—e.g., empty drums, gas cylinders, empty containers. Most damage results from the failure in part or totally of the equipment or containing structure itself.

The blast parameters are usually based on the conservative assumption that the blast strikes the target normal to its surface, so that normal reflection parameters may be used.

The response of a target is a function of the ratio of the blast wave duration and the natural period of vibration of the target (*T/T<sub>n</sub>*). Neither of these parameters can be closely defined.

Calculating the specific response of a specific target can generally be done only approximately. Accuracy is not justified when the blast properties are not well defined. A guide to the damage potential of condensed phase explosive blast is given in Table 23-25 (Scilly and High, "The Blast Effect of Explosions," *Loss Prevention and Safety Promotion in the Process Industries*, European Fed. of Chem. Eng., 337 Event, France, September 1986, table 2). Nuclear data is available (Table 23-26) (Walker, "Estimating Production and Repair Effort in Blast-damaged Petroleum Refineries," *Stanford Research Inst.*, July 1969, fig. 5, p. 45), which is based upon long positive-duration blast (±6 s). This suggests that the Walker data will be conservative for the much shorter duration blast from accidental industrial explosions.

A blast incident overpressure of 35 kN/m<sup>2</sup> (5 psi) is often used to define the region beyond which the damage caused will be minor and not lead to significant involvement of plant and equipment beyond the 35 kN/m<sup>2</sup> boundary.

**Response of People** The greatest hazard to people from blast is generally from the deceleration mechanism after people have been blown off their feet and they become missiles. This occurs at an incident overpressure of about 27 kN/m<sup>2</sup> (4.0 psi) for long positive-duration

**TABLE 23-26 Blast Overpressure Effects on Vulnerable Refinery Parts**

nuclear weapon blasts. People have more blast resistance than most equipment and can survive incident overpressures of 180 kN/m<sup>2</sup> (27 psi) (Bowen, Fletcher, and Richmond, DASA-2113, Washington, D.C., October 1968), even for long-duration blasts.

## PROJECT REVIEW AND AUDIT PROCESSES

**GENERAL REFERENCES:** Center for Chemical Process Safety (CCPS), *Guidelines for Hazard Evaluation Procedures, Second Edition with Worked Examples*, AIChE, September 1992. CCPS, *Guidelines for Technical Management of Chemical Process Safety*, AIChE, 1989. CCPS, *Guidelines for Auditing Process Safety Management Systems*, AIChE, 1993.

**Introduction** Review and audit processes are used in the chemical process industry to evaluate, examine, and verify the design of process equipment, operating procedures, and management systems. These processes assure compliance with company standards and guidelines as well as government regulations. Reviews and audits can encompass the areas of process and personnel safety, environmental and industrial hygiene protection, quality assurance, maintenance procedures, and so on.

A review is a critical examination or evaluation of any operation, procedure, condition, event, or equipment item. Reviews can take many forms and be identified as project reviews, design reviews, safety reviews, pre-start-up reviews, and so on. The following discussion of the review process will deal with project reviews associated with capital projects and focus on the area of process safety.

An audit is a formal, methodical examination and verification of an operation, procedure, condition, event, or series of transactions. The verification element of an audit makes it distinctive from a review. A project review will *recommend* design, procedural, maintenance, and management practices to minimize hazards and reduce risk while meeting company standards and government regulations. An audit will *verify* that the design, the procedures, and the management systems are actually in place, and are being maintained and used as intended. In fact, it is not uncommon for an audit to be done on a review process, to verify that the elements of the review process are being followed.

**Project Review Process** The scope of capital projects can be large, involving the construction of new plants with new technologies and products, or small, involving minor changes to existing facilities. In either case, project safety reviews can be used to evaluate and examine the process design, operating procedures, and process control scheme for process hazards, conformance to company standards and guidelines, and compliance with government regulations. Some objectives of the review process (CCPS, 1992, p. 53) are: (1) identify equipment or process changes that could introduce hazards, (2) eval-

uate the design basis of control and safety systems, (3) evaluate operating procedures for necessary revisions, (4) evaluate the application of new technology and any subsequent hazards, (5) review the adequacy of maintenance and safety inspections, and (6) evaluate the consequences of process deviations and determine if they are acceptable (CCPS, 1989, p. 46).

The project review process should be integrated with the development of the project from the conceptual stage to the start-up stage (CCPS, 1989, p. 46). Figure 23-46 depicts the various stages of a capital project. The size and complexity of a project will determine if the project progresses through all these stages and, in the same manner, determine the number and type of reviews that are needed. The earlier in a project that a review can be used to identify required changes, the less costly the change will be to implement.

As the project progresses, more information is available; therefore, the review technique used can be different at each stage of the project. The use of various hazard evaluation techniques, such as checklist analyses, relative rankings, what-if analyses, and hazard and operability studies, is documented in *Guidelines for Hazard Evaluation Procedures: Second Edition with Worked Examples* (CCPS, 1992). The need to use more quantitative techniques for hazard evaluation may be identified during these reviews, and become an action item for the project team.

The project review process involves multiple steps that should be defined in management guidelines (CCPS, 1993, pp. 57-61). The steps include: (1) review policy, (2) review scheduling, (3) review technique, (4) review team representation, (5) review documentation, (6) review follow-up, (7) review follow-up verification, and (8) review procedures change management. These steps define how a review, whether it be a safety review, environmental review, pre-start-up review, or whatever, is conducted and how closure of review action items is achieved.

**Review Policy** The review policy should establish when project safety reviews should be done. All capital projects, large or small, should have one or more safety reviews during the course of the project. The number and types of review should be stated in a management policy. Any reasons for exceptions to the policy should be documented as well. The policy should address not only projects internal to a company, but also any joint ventures or turnkey projects by outside firms.

**Review Scheduling** A review scheduling procedure should be established that documents who is responsible for initiating the review and when the review(s) should occur during the project. The scheduling needs to balance availability of process information, review technique used, and the impact of potential review action items on project costs (i.e., early enough to minimize the cost of any potential changes

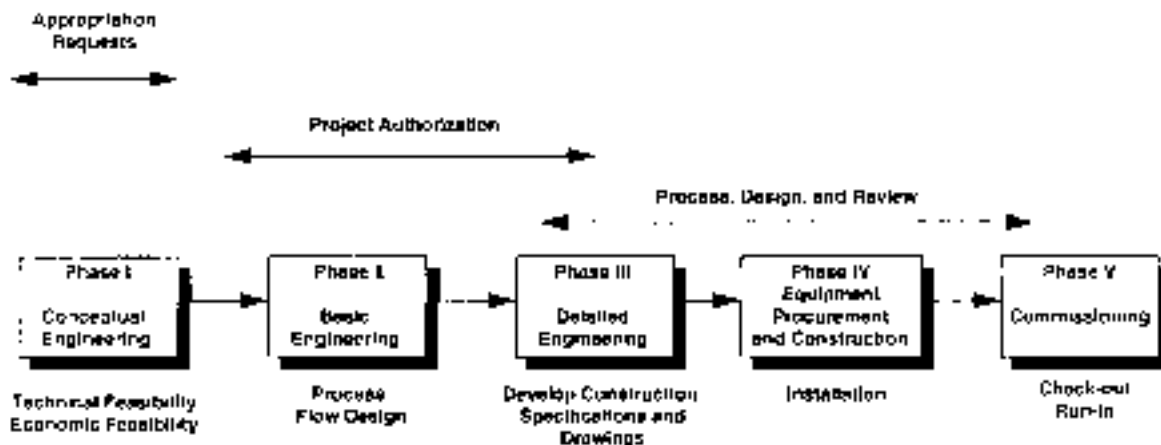

FIG. 23-46 The phases of a capital project. (CCPS, 1989, by permission of AIChE.)

to the process). The actual amount of time needed for the review should also be stated in the procedure. On the basis of the number of project reviews required and the estimated time needed for each review, the project cost estimate should include the cost for project reviews as part of the total cost for the project.

**Review Team** The project review should be conducted by a functionally diverse team. The team should consist of a team leader to organize and lead the team review, a scribe or secretary to record and issue a review summary with action items, and functional experts in fields relevant to the project such as safety, environmental, and industrial hygiene (CCPS, 1993, p. 58). The team leader should be experienced in the use of the selected review technique with leadership skills and no direct involvement with the project under review. The review procedure should address the minimum requirements for team leaders and team members. Some typical requirements could be years of experience, educational background, and training in the review technique. Responsibilities should be clearly defined for initiating the review, assigning the review team, recording the team findings, and monitoring follow-up of team recommendations.

**Review Techniques** The review techniques used at the various stages of a project should be selected based on the amount of process information and detail available. Figure 23-47 depicts some typical review techniques at the various stages of a capital project. A detailed description, including the type and amount of process information required, for each review technique can be found in *Guidelines for Hazard Evaluation Procedures: Second Edition with Worked Examples* (CCPS, 1992). The process information required for the review should be defined and documented in the review guidelines. Up-to-date and accurate process information is essential to conducting a successful review.

**Review Documentation** The project review team leader has the ultimate responsibility for documenting the results of the project

review. This responsibility may be delegated to a team scribe or secretary to record the review minutes and issue a summary report with listed action items. The action items could address exceptions to company or industry standards and government regulations, review team recommendations based on experience and knowledge, and further issues for study that could not be resolved during the review session.

The summary report should have a standard format and could contain a short project scope summary, a listing of review team members by function, a listing of project team members present, a meeting agenda or checklist of topics reviewed by the team, and a list of concerns and action items for project team follow-up. The distribution list for the summary report should be established and include the review team, project team, and any personnel outside the project team who have follow-up responsibilities for any of the action items. Also, include on the distribution list any appropriate management personnel, whether they be project team supervisors, manufacturing managers, or engineering managers. The documentation for the review should be archived in a process plant file with the appropriate records retention time (e.g., the life of the plant).

**Review Follow-up** An important element (maybe the most important) of the review process is the follow-up to action items. The project review will result in a list of potential concerns and action items, but, without follow-up, the issues will never be resolved and implemented. A person(s) should be assigned to each action item, preferably at the time of the project review. The person(s) assigned should have a combination of knowledge, resources, and authority to do a proper job in following up on the action items (CCPS, 1993, p. 59). The total action item list should not be assigned to one person, since it may overwhelm one individual. Depending on the number of action items generated, prioritizing the action item list may be helpful and a responsibility the review team can assume.

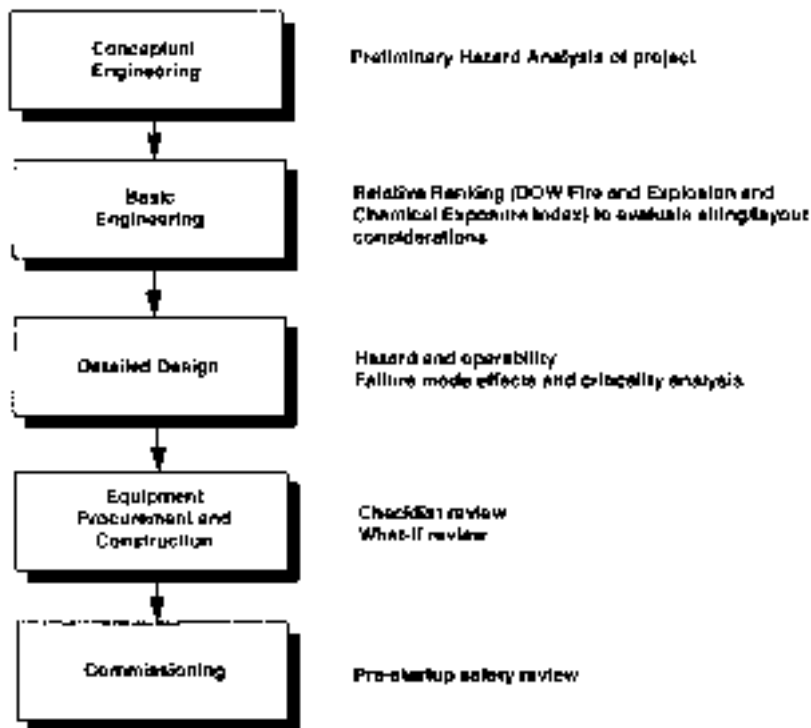

FIG. 23-47 Hazard evaluation at various project stages. (CCPS, 1993, by permission of AIChE.)

Progress on the action items should be documented in periodic progress reports to the review team leader or others assigned that functional responsibility. If no one is assigned the responsibility of tracking this progress, completion of the action list will probably be relegated to a lower priority and not be done.

Changes made to the process as a result of the project review may require a similar review before implementation, especially if the change is significant.

**Review Follow-up Verification** Responsibility should be assigned to verify that any process changes were actually made in the field. This verification can be done by a review team as part of a process pre-start-up review. It could also be part of the project team management responsibility or assigned to a particular functional (i.e., safety and loss prevention) representative. The closure of the review process is complete once implementation is verified.

On rare occasions, the resolution of project review concerns or action items is a point of contention between review team and project team members. In such a case, a management structure must be in place to arbitrate such disputes.

**Review Procedure Change Management** The project review process can require changes in policy and procedures at certain times. Therefore, the procedures should provide a management-of-change mechanism for suggesting changes and assign a person responsible for initiating and implementing any necessary changes.

**Audit Process** Audits in the chemical process industry can be focused on process safety, process safety management, environmental, and health areas. The discussion in this section will focus on the process safety and process safety management area, but it should be recognized that the process can be applied to the other areas as well. "Process safety audits are intended to provide management with increased assurance that operating facilities and process units have

been designed, constructed, operated, and maintained such that the safety and health of employees, customers, communities, and the environment are being properly protected" (CCPS, 1989, p. 133). Process safety management system audits "provide increased assurance that operating units have appropriate systems in place to manage process risk" (CCPS, 1989, p. 130).

The key steps in the audit process are outlined according to pre-audit activities, audit activities, and postaudit activities in Fig. 23-48. These activities are described in detail in *Guidelines for Auditing Process Safety Management Systems* (CCSP, 1993) and will be only briefly discussed in this section.

**Preaudit Process** Prior to the actual on-site audit, some preliminary activities should take place. These activities include selecting the facilities to be audited, scheduling the audit, selecting the audit team, and planning the audit. The selection criteria may be random, based on potential hazards of the facilities or the value of the facilities from a business standpoint. Audit scheduling must account for the availability of key facility personnel and audit team members, operational mode of the facility (i.e., it should be in normal operation), and the lead time required to obtain background information that may require advance visits to the facility and preaudit interviews. The audit team members should possess the technical training and experience to understand the facilities being audited. They should be knowledgeable in the auditing process and in the appropriate regulations and standards that will apply to the facilities. They should also be impartial and objective about audit findings. The audit plan should define the audit scope (what parts of the facility will be covered, what topics, who will do it, etc.), develop an audit protocol that is a step-by-step guide to how the audit is performed, identify any priority topics for coverage, and develop an employee interview schedule.

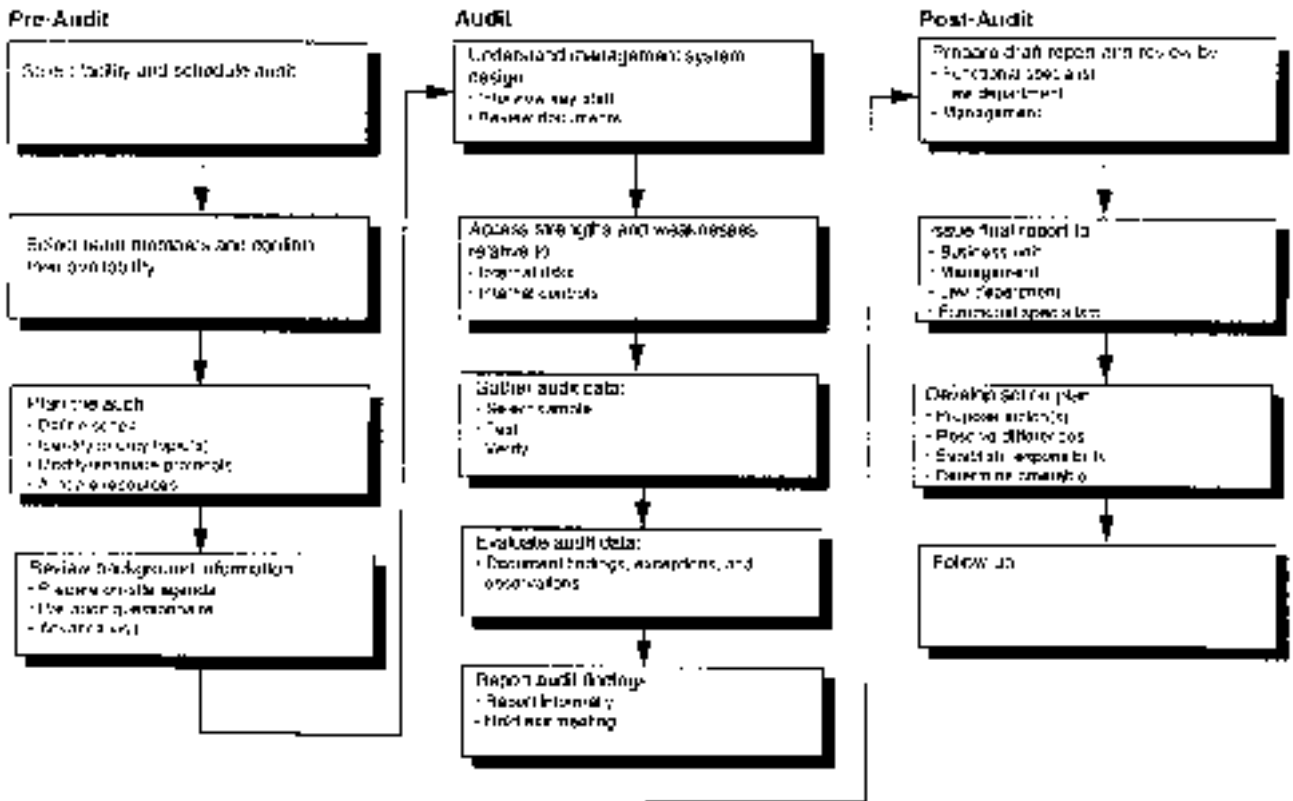

FIG. 23-48 Typical steps in the process safety management audit process. (CCSP, 1993, by permission of AIChE.)

**On-Site Audit Process** An opening meeting with key facility personnel is held at which the audit team covers the objectives and approach for the audit, and the facility personnel provide an overview of the site operations including site safety rules and a site tour. The on-site audit process should then follow five basic steps that include: (1) understanding management systems, (2) evaluating management systems, (3) gathering audit information, (4) evaluating audit information, and (5) reporting audit findings (CCSP, 1993, p. 17).

An understanding of the management systems in place to control and direct the process safety of the facility can be obtained from reading engineering and administrative standards, guidelines, and procedures that should be available in the background information supplied prior to the on-site audit. Informal procedures and guidelines used by the facility may only be discovered in interviews with staff management and operations management. This understanding of the formal and informal management systems is a critical step in the audit process.

The next process step evaluates the process safety management systems to determine if they are adequate to achieve the desired results, and if they are used as intended. This evaluation is highly subjective on the auditor's part. This step sets the stage for the rest of the audit, guiding the auditor's information gathering and focusing attention on critical areas.

Gathering audit data can be accomplished through observations, documents, and interviews. The data obtained is used to verify and validate that the process safety management systems are implemented and functioning as designed. Data gathering can be aided by the use of audit samples, where a representative number of items are audited to draw a conclusion, and by using self-evaluation questionnaires.

The audit data can now be evaluated, resulting in audit findings (i.e., conclusions both positive and negative). The audit team should confirm that sufficient data has been collected to support each finding. Additional data may need to be gathered if the team decides a preliminary finding needs to be strengthened. The conclusions drawn from the data evaluation should be a team consensus.

The reporting step of the on-site audit should be planned to avoid any surprises to facility personnel. Reporting sessions should be held at the end of each audit day to inform facility personnel of the findings, clear up any misunderstandings of the data, and help redirect

the audit team, if necessary. The on-site audit should end with a well-planned exit or closeout meeting between the audit team and facility personnel. All the findings of the audit team should be presented at this meeting. This verbal report is the opportunity for clarification of any ambiguities and determination of the final disposition of the findings (written audit report, for local attention only, etc.).

**Postaudit Process** The postaudit process consists of preparation of a draft report, preparation of a final report, development of action plans, and follow-up. A draft report of the audit findings should be prepared shortly after the completion of the on-site audit. The draft report usually undergoes review and comment by facility personnel involved with the audit, experienced auditors not involved with the subject audit, functional specialists, and attorneys. The review of the draft report is done to assure that a clear, concise, and accurate report is issued, and not to modify or change the findings. Once this review procedure is completed, a final report can be issued and distributed based on a distribution list provided by the facility personnel. The final audit report should be issued in a timely manner and meet the time requirement specified in the audit plan.

An action plan should be developed by the appropriate personnel of the audited facility to address any deficiencies stated in the audit report. Action plans should state what is to be done, who is responsible for getting it done, and when it is to be completed. Rationale for not taking any action for any of the stated deficiencies should also be documented. The action plan is an important step in closing the audit process.

It would not be unusual for some action plans to take a long time to complete. When extended implementation time is necessary, a follow-up mechanism should be used to document progress and show that an effort is being made to resolve the issues. Periodic (i.e., quarterly, semiannually) progress reports should be used as a follow-up method to ensure implementation. Future audits of the facility should include confirmation of the implementation of previous audit action plans.

The final audit report, action plans, progress reports, and any closure report should be retained by the facility based on the facility record retention policy. Typically, these items will be retained until future audit documentation replaces them. In some cases, audit records are retained for the life of the plant.

## SAFETY EQUIPMENT, PROCESS DESIGN, AND OPERATION

### PRESSURE RELIEF SYSTEMS

**Introduction** All process designs should attempt to arrive at an inherently safe facility. Incorporating safety features that are intrinsic (built-in) rather than extrinsic (added-on) to the basic design, together with the use of high-integrity equipment and piping, provides the first lines of defense against the dramatic, often catastrophic effects of an overpressure and subsequent rupture. In recent years, many companies have incorporated the principles of depressurizing or instrumental shutdown of key equipment as a means to control a release and avoid the actuation of pressure relief devices. This minimizes the probability of failure of the device, because, once used, the device may no longer be dependable. Since maintenance of relief devices can be sporadic, this redundancy provides yet another layer of safety. However, regardless of the number of lines of defense and depressur-

izing systems in place, overpressure protection must still be provided. Emergency pressure relief systems are intended to provide the last line of protection and thus must be designed for high reliability, even though they will have to function infrequently.

Self-actuated pressure relief systems must be designed to limit the pressure rise that can occur as a result of overcompressing, overfilling, or overheating either an inert or a chemically reactive medium in a closed system. Pressure generation is usually the result of either expansion of a single-phase medium (by material addition and/or heating) or a shift of the phase equilibrium in a multiphase medium (as a result of composition and/or temperature changes, particularly in the case of a reactive system). These mechanisms of pressure generation differ from what is commonly referred to as explosion venting. Events such as dust explosions and flammable vapor deflagrations propagate nonuniformly from a point of initiation, generating pressure or shock waves. Such venting problems are not included in these discussions.

**Relief System Terminology** Refer to API-RP520 Part I for complete terminology.

**Accumulation** The rise of pressure above the MAWP of the protected system, usually expressed as a percentage of the gauge MAWP. Maximum allowable accumulations are established by applicable codes for emergency operating and fire contingencies.

**Backpressure** The pressure existing at the outlet of a relief device. The value under no-flow conditions is superimposed backpressure. The value under flowing conditions consists of both

superimposed backpressure and built-up pressure due to piping pressure drop.

**Blowdown** The reduction in flowing pressure below the set point required for a PRV to close.

**Design pressure** The design pressure used to determine the minimum thickness of a vessel component and possibly used in place of MAWP where the latter has not been established. It is equal to or less than the MAWP. It is the pressure specified on the equipment purchase order.

**Maximum allowable working pressure (MAWP)** The maximum allowed pressure at the top of the vessel in its normal operating position at the operating temperature specified for that pressure.

**Overpressure** A pressure increase above the set point during relief flow, usually expressed as a percentage of the differential set pressure.

**Pressure relief valve (PRV)** A pressure relief device designed to open and relieve excess pressure and to reclose after normal conditions have been restored. PRV is a generic term applied to *relief valve* (set up for liquid flow), *safety valve* (set up for gas or vapor flow), and *safety relief valve* (set up for either liquid or compressible flow).

**Relieving pressure** Set pressure plus the overpressure.

**Rupture disk** A non-reclosing pressure relief device actuated by static differential pressure and designed to function by the bursting of a pressure-containing disk.

**Set pressure** The inlet gauge pressure at which a PRV will start to open (or a rupture disk will burst) under service conditions of temperature and backpressure.

**Codes, Standards, and Guidelines** Industry practice is to conform to the applicable regulations, codes, and recommended practices. In many cases, these will provide different guidelines. A suggested approach would be to review all applicable codes, standards, and recommended practices prior to choosing a design basis. The Design Institute for Emergency Relief Systems (DIERS) was established by AIChE to address sizing aspects of relief system for two-phase, vapor-liquid flashing flow regimes. The DIERS Project Manual (*Emergency Relief System Design Using DIERS Technology*, 1982) and the CCPS Guidelines (*Guidelines for Pressure Relief and Effluent Handling Systems*, 1998) are the generally accepted industry standard for two-phase relief venting.

NFPA 30 and API Standard 2000 provide guidance for design of overpressure protection involving storage tanks that operate at or near atmospheric pressure. In particular, NFPA 30 focuses on flammability issues, while API 2000 addresses both pressure and vacuum requirements. The ASME code (Sections I and VIII) and API RP 520 are the primary references for pressure relief device sizing requirements.

Designers of emergency pressure relief systems should be familiar with the following list of regulations, codes of practice, and industry standards and guidelines in the United States.

API RP 520. *Sizing, Selection, and Installation of Pressure-Relieving Devices in Refineries*. Part I, *Sizing and Selection*, 7th ed., January 2000, and Part II, *Installation*, 4th ed., December 1994. American Petroleum Institute, Washington.

API RP 521, 1997. *Guide for Pressure-Relieving and Depressuring Systems*, 4th ed. American Petroleum Institute, Washington.

**Relief Design Scenarios** The most difficult part of designing an adequate emergency pressure relief system lies in determining the emergency events (credible design scenarios) for which to design. The difficulty arises primarily because the identification of credible design scenarios usually involves highly subjective judgments, which are often influenced by economic situations. Unfortunately, there exists no universally accepted list of credible design scenarios. Relief systems must be designed for the credible chain of events that results in the most severe venting requirements (worst credible scenario). Credibility is judged primarily by the number and the time frame of causative failures required to generate the postulated emergency. Only totally independent equipment or human failures should be considered when judging credibility. A failure resulting from another failure is an effect, rather than an independent causative factor. A suggested guideline for assessing credibility as a function of the number and time frames of independent causative events is as follows:

- Any single failure is *credible*.
- Two or more simultaneous failures are *not credible*.
- Two events in sequence are *credible*.
- Three or more events in sequence are *not credible*.

The first step in scenario selection is to identify all the credible emergencies by using the preceding guidelines (or a similar set). This is perhaps best accomplished by identifying all the possible sources of pressure and vacuum. Table 23-27 lists a number of commonly existing pressure and vacuum sources.

**Fire** The main consequence of fire exposure is heat input causing thermal expansion, vaporization, or thermally induced runaway reaction and decomposition resulting in a pressure rise. An additional result of fire exposure is the possibility of overheating the wall of the equipment in the vapor space where the wall is not cooled by the liquid. In this case, the vessel wall may fail due to the high temperature, even though the relief system is operating. Hence API RP-521 recommends vapor depressurizing facilities for high-pressure services (greater than 17 bar or 250 psig). Guidelines for estimating the heat input from a fire are found in API Recommended Practices, NFPA 30 (for bulk storage tanks), OSHA 1910.106, and corporate engineering standards. In determining the heat input from fire exposure, NFPA allows credit for application of water spray to a vessel; API allows no such credit.

Pressure vessels (including heat exchangers and air coolers) in a plant handling flammable fluids are subject to potential exposure to external fire. A vessel or group of vessels which could be exposed to a

**TABLE 23-27 Common Sources of Pressure and Vacuum**

| • Vapor condensation                        |

pool fire must be protected by pressure relief device(s). Additional protection to reduce the device relief load can be provided by insulation, water spray, drainage, or remote-controlled depressurizing devices. Plant layout should consider spacing requirements, such as those set forth by NFPA, API, Industrial Risk Insurers, or Factory Mutual, and must include accessibility for firefighting personnel and equipment. Several pieces of equipment located adjacent to each other that cannot be isolated by shutoff valves can be protected by a common relief device, providing the interconnecting piping is large enough to handle the required relief load and the relief set pressure is no higher than the minimum MAWP of these pieces of equipment.

**Operational Failures** A number of scenarios of various operational failures may result in the generation of overpressure conditions:

- **Blocked outlet** Operation or maintenance errors (especially following a plant turnaround) can block the outlet of a liquid or vapor stream from a piece of process equipment, resulting in an overpressure condition.
- **Opening a manual valve** Manual valves which are normally closed to isolate two or more pieces of equipment or process streams can be inadvertently opened, causing the release of a high-pressure stream or resulting in vacuum conditions.
- **Cooling water failure** The loss of cooling water is one of the more commonly encountered causes of overpressurization. Different scenarios should be considered for this event, depending on whether the failure affects a single piece of equipment (or process unit) or is plantwide.
- **Power failure** The loss of power will shut down all motor-driven rotating equipment, including pumps, compressors, air coolers, and vessel agitators.
- **Instrument air failure** The consequences of the loss of instrument air should be evaluated in conjunction with the failure mode of the control valve actuators. It should not be assumed that the correct air failure response will occur on these control valves, as some valves may stick in their last operating position.
- **Thermal expansion** Equipment and pipelines that are liquid-full under normal operating conditions are subject to hydraulic expansion if the temperature increases. Common sources of heat that can result in high pressures due to thermal expansion include solar radiation, steam or other heated tracing, heating coils, and heat transfer from other pieces of equipment.
- **Vacuum** Vacuum conditions in process equipment can develop due to a wide variety of situations, including instrument malfunction, draining or removing liquid with venting, shutting off purge steam without pressurizing with noncondensable vapors, extreme cold ambient temperatures resulting in subatmospheric vapor pressures, and water addition to vessels that have been steam-purged. If vacuum conditions can develop, then either the equipment must be designed for vacuum conditions or a vacuum relief system must be installed.

**Equipment Failure** Most equipment failures that can lead to overpressure situations involve the rupture or break of internal tubes inside heat exchangers and other vessels and the failure of valves and regulators. Heat exchangers and other vessels should be protected with a relief system of sufficient capacity to avoid overpressure in case of internal failure. API RP 521 presents guidance in determining these requirements, including criteria for deciding when a full tube rupture is likely. In cases involving the failure of control valves and regulators, it is important to evaluate both the fail-open and fail-closed positions.

**Runaway Reactions** Runaway temperature and pressure in process vessels can occur as a result of many factors, including loss of cooling, feed or quench failure, excessive feed rates or temperatures, contaminants, catalyst problems, and agitation failure. Of major concern is the high rate of energy release in runaway reactions and/or formation of gaseous products, which generally cause a rapid pressure rise in the equipment. To properly assess these effects, the reaction kinetics must be either known or obtained experimentally (see "Reactivity Testing" in the earlier "Chemical Reactivity" subsection for a description of adiabatic calorimeters for runaway reactions). In general, a lower relief set pressure (much below the equipment MAWP) is desirable for these runaway reaction systems in order to relieve the

system at a lower reaction rate, since most reactions are Arrhenius in behavior.

**Pressure Relief Devices** The most common method of overpressure protection is through the use of safety relief valves and/or rupture disks which discharge into a containment vessel, a disposal system, or directly to the atmosphere. Table 23-28 summarizes some of the device characteristics and the advantages.

**Safety Relief Valves (SRVs)** Conventional safety relief valves are used in systems where built-up backpressures typically do not exceed 10 percent of the set pressure. The spring setting of the valve is reduced by the amount of superimposed backpressure expected. Higher built-up backpressures can result in a complete loss of continuous valve relief capacity. The designer must examine the effects of other relieving devices connected to a common header on the performance of each valve. Some mechanical considerations of conventional relief valves are presented in the ASME code; however, the manufacturer should be consulted for specific details.

Balanced safety relief valves may be used in systems where built-up and/or superimposed backpressure is high or variable. In general, the capacity of a balanced valve is not significantly affected by backpressures below 30 percent of the set pressure. Most manufacturers recommend keeping the backpressure on balanced valves below 45 to 50 percent of the set pressure. Consult API-526 and valve manufacturers for the maximum outlet pressure limit for bellows-type SRVs.

For both conventional and balanced SRVs, the inlet pressure loss, including the mounting nozzle entrance loss, rupture disk flow resistance, and inlet pipe friction, is recommended to stay below 3 percent of the differential set pressure, or else valve instability may occur, resulting in degraded relief capacity.

**Pilot-Operated Relief Valves** In a pilot-operated relief valve, the main valve is combined with and controlled by a smaller, self-actuating pressure relief valve. The pilot is a spring-loaded valve that senses the process pressure and opens the main valve by lowering the pressure on the top of an unbalanced piston, diaphragm, or bellows of the main valve. Once the process pressure is lowered to the blowdown pressure, the pilot closes the main valve by permitting the pressure in the top of the main valve to increase. Pilot-operated relief valves are commonly used in clean, low-pressure services and in services where a large relieving area at high set pressures is required. The set pressure of this type of valve can be close to the operating pressure. Pilot-operated valves are frequently chosen when operating pressures are within 5 percent of set pressures and a close tolerance valve is required.

**Rupture Disks** A rupture disk is a non-reclosing device designed to function by the bursting of a pressure-retaining disk. This assembly consists of a thin, circular membrane usually made of metal, plastic, or graphite that is firmly clamped in a disk holder. When the process reaches the bursting pressure of the disk, the disk ruptures and releases the pressure. Rupture disks can be installed alone or in combination with other types of devices. Once blown, rupture disks do not reseal; thus, the entire contents of the upstream process equipment will be vented. Rupture disks of nonfragmented type are commonly used in series (upstream) with a safety relief valve to prevent corrosive

fluids from contacting the metal parts of the valve. In addition, this combination is a reclosing system.

The burst tolerances of rupture disks are typically about  $\pm 5$  percent for set pressures above 2.76 barg (40 psig). Consult API-520-I (Section 2.3.6.1) on the proper selection and burst setting of the rupture disks.

**Pressure Vacuum Relief Valves** For applications involving atmospheric and low-pressure storage tanks, pressure-vacuum relief valves (PVRVs) are used to provide pressure relief. Such devices are not included in the scope of ASME Section VIII and thus are not Code-certified; hence they are used mostly in non-Coded vessels (<1.03-barg or 15-psig design). These units combine both a pressure and a vacuum relief valve into a single assembly that mounts on a nozzle on top of the tank and are usually sized to handle the normal in-breathing and out-breathing requirements.

**Sizing of Pressure Relief Systems** A critical point in design is to determine whether the relief system must be sized for single-phase or two-phase relief flow. Two-phase flow frequently occurs during a runaway, but it can also occur in nonreactive systems such as vessels with gas spargers, vessels experiencing high heat input rates, or systems containing known foaming agents such as latex. The *drift flux* methodology (Zuber and Findlay, "Average Volumetric Concentration in Two-Phase Flow Systems," *Trans. ASME J. Heat Transfer*, pp. 453-468, November 1965; Wallis, *One-Dimensional Two-Phase Flow*, McGraw-Hill, New York, 1969) has been extended and applied to both the volumetric heating case (uniform vapor generation throughout the liquid) and wall heating case (vaporization occurring only at vessel wall) in the DIERS (Design Institute for Emergency Relief Systems) study (DIERS, 1992). The DIERS methodology is important as a means of addressing situations, such as two-phase flow, not covered adequately by current ASME and API methods. The recent CCPS Guidelines (CCPS, 1998) is the best source of updated information on these methods. For a top-vented vessel, the important mechanism for the liquid carryover resulting in two-phase relief is *boilover*. The vessel hydrodynamic model based on drift flux formulation is used to estimate the quality (i.e., vapor mass fraction) entering the vent system. The churn-turbulent regime vessel model is generally reserved for nonfoaming and nonviscous liquids. This regime would yield the highest degree of vapor-liquid disengagement. The bubbly regime vessel model is generally applied to foamy liquids and viscous systems. The bubbly regime would yield only limited disengagement in the vessel. Finally, a conservative but often realistic case for runaway reactive systems is the homogeneous (or uniform froth) vessel model. This model assumes no vapor-liquid disengagement inside the vessel, an idealized assumption, but it leads to much simpler sizing equations.

**Required Relief Rate** The required relief rate is the vent rate  $W$  (kg) required to remove the volume being generated within the protected equipment when the equipment is at its highest allowed pressure:

$$W_{\text{req}} = \frac{\text{net volume generation rate}}{\text{specific volume of vent stream}} \quad (23-89)$$

For steady-state design scenarios, the required vent rate, once determined, provides the capacity information needed to properly size the relief device and associated piping. For situations that are transient (e.g., two-phase venting of a runaway reactor), the required vent rate would require the simultaneous solution of the applicable material and energy balances on the equipment together with the in-vessel hydrodynamic model. Special cases yielding simplified solutions are given below. For clarity, nonreactive systems and reactive systems are presented separately.

#### Nonreactive Systems

**Consider constant flow into protected equipment (blocked outlet).** For the steady-state design scenario with a constant flow of fluid  $W_{\text{in}}$  (kg/s) from a pressure source that is above the maximum allowed pressure in the protected equipment, volume is being generated within the equipment at a rate of  $W_{\text{in}}/\rho_{\text{in}}$ , where  $\rho_{\text{in}}$  (kg/m<sup>3</sup>) is the incoming fluid density evaluated at the maximum allowed pressure. Denoting  $\rho_{\text{out}}$  (kg/m<sup>3</sup>) as the vent stream fluid density, Eq. (23-89)

then yields the required vent rate:

$$W_{\text{req}} = \frac{W_{\text{in}}}{\rho_{\text{in}}} \rho_{\text{out}} \quad (23-90)$$

**Consider constant heat input into protected equipment.** If the addition of heat to the equipment does not cause the fluid to boil, then the volume generation rate is the thermal expansion rate of the fluid:

$$W_{\text{req}} = \frac{q\beta}{C_p} \quad (23-91)$$

where  $q$  is the heat input rate (J/s),  $\beta$  is the coefficient of volumetric expansion at constant pressure ( $^{\circ}\text{C}^{-1}$ ), and  $C_p$  is the constant-pressure specific heat [J/(kg $\cdot^{\circ}\text{C}$ )].

The properties are evaluated at maximum allowed pressure conditions. For liquids,  $\beta$  can typically be evaluated from the specific volume change over a 5 $^{\circ}\text{C}$  temperature increment. For ideal gases, Eq. (23-91) becomes

$$W_{\text{req}} = \frac{q}{C_p T} \quad (23-92)$$

where  $T$  is the absolute temperature (K).

If the fluid is at its boiling point, then volume is generated through the phase change that occurs upon vaporization. For *nonfoamy fluids*, vents sized for all-vapor relief are adequate, even if some initial two-phase venting is predicted. The required vent rate based on the volumetric rate balance criterion of Eq. (23-89) is given for a single-component fluid as (Leung, 1986a)

$$W_{\text{req}} = \frac{q}{h_{fg}} \left( \frac{v_{fg}}{v_g} \right) \quad (23-93)$$

where  $h_{fg}$  is the latent heat of vaporization (J/kg),  $v_g$  is the vapor specific volume (m<sup>3</sup>/kg),  $v_{fg}$  is the specific volume increase upon vaporization =  $v_g - v_f$  (m<sup>3</sup>/kg), and  $v_f$  is the liquid specific volume (m<sup>3</sup>/kg).

Near the critical region, the property ratio  $h_{fg}/v_{fg}$  can be replaced by  $T(dP/dT)_{\text{sat}}$  via the Clapeyron relation since both  $h_{fg}$  and  $v_{fg}$  are approaching zero. Here  $(dP/dT)_{\text{sat}}$  is the slope of the vapor-pressure curve and has units of Pa/K. For multicomponent fluids, Eq. (23-93) is evaluated for each major component (> 10% wt), and the largest single-component venting requirement is used. Refer to CCPS Guidelines (1998) for more complex schemes.

For *foamy fluids*, the homogeneous vessel model with volumetric heating assumption is used (Leung, 1986a):

$$W(T_p - T_s) = \frac{q}{C_p} \left( \ln \frac{m_0 q v_{fg}}{W V h_{fg}} - 1 \right) + \frac{W V h_{fg}}{m_0 C_p v_{fg}} \quad (23-94)$$

where  $W$  is the vent rate (kg/s),  $T_p$  is the temperature at peak pressure ( $^{\circ}\text{C}$ ),  $T_s$  is the temperature at set pressure ( $^{\circ}\text{C}$ ),  $m_0$  is the initial mass in system (kg),  $V$  is the equipment (vessel) volume (m<sup>3</sup>),  $q$  is the heat input rate (J/s), and  $C_p$  is the constant-pressure liquid specific heat [J/(kg $\cdot^{\circ}\text{C}$ )].

Note that Eq. (23-94) is implicit in  $W$ ; a trial-and-error solution method is required. This equation is applicable for single-component or pseudo-one-component systems. For the latter,  $h_{fg}$  is defined to be the enthalpy (heat) required to vaporize a unit mass of liquid at equilibrium vapor composition.

Analytical equations have been presented for both the bubbly regime and churn-turbulent regime; see Leung (Leung, "Overpressure During Emergency Relief Venting in Bubbly and Churn-Turbulent Flow," *AIChE J.* 33(6), pp. 952-958, 1987) and Dalessandro (Dalessandro, "Emergency Venting Requirements for Tempered Systems Considering Partial Vapor-Liquid Separation with Disengagement Parameters Greater than Unity, Part I: Model Development, Part II: Application," *Process Safety Prog.* 23, pp. 1-15 and 86-98, 2004).

**Reactive Systems** Exothermic runaway (uncontrolled chemical) reactions add considerable complexity. Note that external heating (such as a fire) on a vessel containing unstable compounds would fall into this category. The added complications are due to the following:

1. Reaction rate varies exponentially with temperature.
2. Exothermic heat release rates are time-varying.
3. Volatile or noncondensable gas can be generated (in decomposition).
4. Composition change causes shift in boiling point curve.
5. Viscosity increases due to polymerization.

In dealing with such complexity, DIERS has developed a special bench-scale apparatus commercialized by Fauske & Associates, LLC, as the Vent Sizing Package 2 (VSP2™). The design and operation are described in several references [Fauske and Leung, "New Experimental Technique for Characterizing Runaway Chemical Reactions," *Chem. Eng. Prog.*, **80**(8), pp. 39–46, 1985; Leung, Fauske, and Fisher, "Thermal Runaway Reactions in a Low Thermal Inertia Apparatus," *Thermochimica Acta*, **104**, pp. 13–29, 1986; DIERS, 1992; CCPS, 1998]. This adiabatic calorimeter has been extensively used to obtain the above key information for pressure relief design. Upset scenarios such as external heating, overcharge of reactants, or loss of cooling can be directly simulated in this apparatus. Two special-case solutions are given here.

**For boiling liquid reactive systems**, an analytical method yielding closed-form integral equations for homogeneous vessel two-phase relief has been used for some time (Leung, 1986a). Simplifying assumptions are that (1) the vent rate is taken as constant with time, (2) average values of heat release rate per unit mass and physical properties can be used, (3) there is constant or decreasing system volatility, and (4) a pseudo-one-component approach is taken. The required vent rate is

$$W_{req} = \frac{m_0 C_p (dT/dt)_{av}}{[(V/m_0)/(h_{fg}/v_{fg})]^{1/2} + (C_p \Delta T)^{1/2}} \quad (23-95)$$

where  $\Delta T = T_p - T_s$  is the "overtemperature" (°C) corresponding to the overpressure  $\Delta P$  selected, and  $(dT/dt)_{av}$  is the average temperature rise rate (°C/s).

The average  $dT/dt$  is typically an arithmetic average between the value at set pressure and the value at peak allowed pressure. The properties  $C_p$ ,  $h_{fg}$ ,  $v_{fg}$  either can be evaluated at the set conditions or can be taken as the average values between the set condition and the peak allowed pressure condition. Alternatively, the term  $h_{fg}/v_{fg}$  in Eq. (23-95) can be replaced by  $T(dp/dT)_{sat}$  via the Clapeyron relation. This holds reasonably well for a multicomponent system of near constant volatility. Such an application permits direct use of the experimental pressure-temperature data obtained from a closed-system runaway VSP2 test. This form of Eq. (23-95) has been used to demonstrate the advantageous reduction in both vent rate and vent area with allowable overpressure (Leung, 1986a).

For partial disengagement venting models (in bubbly and churn-turbulent regimes), refer to publications by Leung (1987) and Dalessandro (2004).

The special case of **gas generating reactive systems** is for a decomposition reaction with negligible gas solubility in the liquid and no significant latent heat effects. Such a reaction will proceed to the maximum rate whether vented or not. The main purpose of venting is to limit the pressure rise in these "gassy" systems. The maximum gas generation rate is usually obtained from the pressure rise rate data in the DIERS-type apparatus. At the peak allowed pressure  $P_m$ , the volumetric gas generation rate for the protected equipment is given by

$$Q_{g,max} = \frac{m_0}{m_t} \frac{V_t}{P_m} \left( \frac{dP}{dt} \right)_{max} \quad (23-96)$$

where  $m_0$  is the mass in protected equipment (kg),  $m_t$  is the sample mass in test apparatus (kg),  $V_t$  is the volume occupied by gas in test apparatus ( $m^3$ ),  $P_m$  is the peak allowed pressure in equipment (Pa, psia), and  $(dP/dt)_{max}$  is the maximum pressure rise rate measured in test apparatus (Pa/s, psi/s). Note that consistent pressure units can be used for  $P_m$  and  $dP/dt$  here. The required vent rate based on the volumetric rate balance criterion of Eq. (23-89) is given by

$$W_{req}^0 = \frac{Q_{g,max}}{V/m_0} \quad (23-97)$$

However, this vent rate assumes homogeneous vessel venting at the peak allowed pressure with no prior loss of mass. A less conservative design would consider the mass loss during the overpressure venting interval [Leung, "Venting of Runaway Reactions with Gas Generation," *AIChE J.*, **38**(5), pp. 723–732, 1992].

**Relief System Flow Capacity** This subsection establishes the relation between relief system configuration and flow capacity in order to determine the size required for a given vent rate. The mass flow rate  $W$  through a given relief system geometry, in general, requires a trial-and-error approach when the system configuration contains more than a single diameter. The generalized approach is to assume a flow rate  $W$ —this is usually governed by the limiting area such as the orifice or nozzle in a pressure relief valve (PRV) or the rupture disk (RD)—and calculate the resulting pressure profiles down the system until the final discharge pressure matches the specified value. If choked flow is encountered at any area enlargement location in the vent system, then the pressure just after the choking location is determined by calculating back up the larger pipe from a downstream point of specified pressure.

The treatment of vent flow calculations in most typical relief system configurations involves two classes of computational models: flow through nozzles and frictional flow in pipes.

The flow path in well-formed nozzles [ideal (**frictionless**) flow] follows smoothly along the nozzle contour without flow separation. The effects of small imperfections and small frictional losses are accounted for by correcting the ideal nozzle flow by an empirically determined coefficient of discharge  $K_d$ . This applies to PRV geometry. The acceleration of a fluid initially at rest to flowing conditions in an ideal nozzle is given by

$$-\frac{G^2 v}{2} = \int_{P_0}^{P_1} v \, dP \quad (23-98)$$

where  $P_0$  is the stagnation pressure of the fluid,  $P_1$  is the static pressure at the minimum flow area called the *throat*,  $G$  is the mass flux [ $\text{kg}/(\text{m}^2 \cdot \text{s})$ ], and  $v$  is the fluid specific volume ( $\text{m}^3/\text{kg}$ ). If the fluid is compressible, the flow will increase to a maximum value as the downstream pressure is reduced, and any further decrease in the downstream pressure will not affect the flow. This maximum flow condition is referred to as the *critical* (or *choked*) condition. The flow and pressure at this condition are related by

$$G_c = \sqrt{\frac{-1}{(dv/dP)_s}} \quad (23-99)$$

The subscript  $s$  denotes an isentropic path for ideal nozzle flow. For ideal gas with  $Pv^k = \text{constant}$ , substitution of this isentropic expansion law into Eq. (23-98) yields the following critical pressure ratio  $P_c/P_0$  and critical flow rate  $G_c$ :

$$\frac{P_c}{P_0} = \left( \frac{2}{k+1} \right)^{k/(k-1)} \quad (23-100)$$

$$G_c = \left[ k \left( \frac{2}{k+1} \right)^{(k+1)/(k-1)} \right]^{1/2} \sqrt{\frac{P_0}{v_0}} \quad (23-101)$$

where  $k$  is the isentropic expansion exponent for ideal gas ( $k = C_p/C_v$ ),  $P_c$  is the choking pressure at throat (Pa),  $P_0$  is the stagnation inlet pressure (Pa), and  $v_0$  is the ideal gas specific volume at  $P_0$  ( $\text{m}^3/\text{kg}$ ).

Thus for a PRV system, the following relief rate formula (for choked flow) is given in SI units ( $\text{kg/s}$ ,  $\text{m}^2$ ,  $\text{N/m}^2$ , K) in API-520-I (2000):

$$W = K_d K_b A P_0 \left( \frac{M_{tw}}{RT_0 Z} \right)^{1/2} \left[ k \left( \frac{2}{k+1} \right)^{(k+1)/(k-1)} \right]^{1/2} \quad (23-102)$$

where  $K_d$  is the discharge coefficient of PRV nozzle (orifice),  $K_b$  is the capacity correction factor due to backpressure (consult API-520-1),  $A$  is the PRV orifice area ( $m^2$ ),  $M_w$  is the molecular weight,  $R$  is the gas constant,  $T_0$  is the absolute temperature at inlet (K), and  $Z$  is the compressibility. For nonideal gas at near thermodynamic critical or supercritical region, special treatments other than simply applying the  $Z$  factor as in Eq. (23-102) are necessary [see Leung and Epstein, "A Generalized Critical Flow Model for Non-ideal Gases," *AICHE J.* 34(9), pp. 1568-1572, 1988; and CCPS, 1998].

The treatment for two-phase relief is more involved due to the presence of slip and thermodynamic nonequilibrium between the two phases. However, for flow capacity evaluation, the traditional homogeneous (no slip) equilibrium model (HEM) is recommended (DIERS, 1992; CCPS, 1998). For a two-phase flashing system (both single-component and multicomponent), the  $P$ - $v$  relation can be obtained from adiabatic flash calculations—strictly speaking under constant-entropy, but constant-enthalpy flash computations are adequate for use in numerical integration of Eq. (23-98). A particularly useful simplification is the *omega* method by Leung (1986b; see the earlier subsection "Discharge Rates from Punctured Lines and Vessels" for more discussion), where a  $P$ - $v$  relation for a two-phase fluid expansion is written as

$$\frac{v}{v_0} = \omega \left( \frac{P_0}{P} - 1 \right) + 1 \quad (23-103)$$

For a single-component or a pseudo-one-component fluid, the dimensionless parameter  $\omega$  is evaluated at the inlet conditions (subscript 0) from (Leung, 1996)

$$\omega = \alpha_0 \left( 1 - 2 \frac{P_0 v_{f0}}{h_{f0}} \right) + \frac{C_{p0} T_0 P_0}{v_0} \left( \frac{v_{f0}}{h_{f0}} \right)^2 \quad (23-104)$$

For multicomponent systems with boiling range greater than 80°C, a single adiabatic flash calculation to 80 to 90 percent of the inlet pressure  $P_0$  yields the two-phase specific volume  $v_1$  at pressure  $P_1$ , and  $\omega$  is calculated from (Nazario and Leung, "Sizing Pressure Relief Valves in Flashing and Two-Phase Service: An Alternative Procedure," *J. Loss Prev. Process Ind.* 5(5), pp. 263-269, 1992)

$$\omega = \frac{v_1/v_0 - 1}{P_0/P - 1} \quad (23-105)$$

For the case of a noncondensable gas and a nonflashing liquid (a nonflashing two-phase fluid),  $\omega$  is simply defined by (Leung, 1996)

$$\omega = \frac{\alpha_0}{\Gamma} \quad (23-106)$$

where the two-phase isentropic expansion exponent for a thermal equilibrium process is given by

$$\Gamma = \frac{x C_{pg} + (1-x) C_{pf}}{x C_{vg} + (1-x) C_{vf}} \quad (23-107)$$

Note that for most cases of interest,  $\Gamma$  is close to unity since the flowing gas mass fraction  $x \ll 1$ . For the case of frozen flow (i.e., no heat transfer between the two phases),  $\Gamma$  would be replaced by  $k$  (or  $C_{pg}/C_{vg}$ ) in Eq. (23-106). However, the difference between the two limiting cases is small (< 10 percent) in terms of the flow capacity [Leung and Epstein, "A Generalized Correlation for Two-Phase Nonflashing Homogeneous Choked Flow," *Trans. ASME J. Heat Transfer* 112 (May), pp. 528-530, 1990].

With the  $P$ - $v$  relation given by Eq. (23-103), Eq. (23-98) can be integrated to give a generalized equation for flow through an ideal nozzle

$$\frac{G}{\sqrt{P_0 v_0}} = \frac{[-2[\omega \ln(P/P_0)] + (\omega - 1)(1 - P/P_0)]^{0.5}}{\omega(P_0/P - 1) + 1} \quad (23-108)$$

The maximum (critical) or choked flow condition occurs at the critical pressure ratio  $P_c/P_0$  from solving (Leung, 1986a)

$$\left( \frac{P_c}{P_0} \right)^2 + (\omega^2 - 2\omega) \left( 1 - \frac{P_c}{P_0} \right)^2 + 2\omega^2 \ln \frac{P_c}{P_0} + 2\omega^2 \left( 1 - \frac{P_c}{P_0} \right) = 0 \quad (23-109)$$

The critical mass flux  $G_c$  is given by the dimensionless form

$$\frac{G_c}{\sqrt{P_0 v_0}} = \frac{P_c/P_0}{\sqrt{\omega}} \quad (23-110)$$

If  $P_c > P_b$ , the backpressure, the flow is choked, and Eq. (23-110) yields the critical mass flux. Otherwise,  $P_c < P_b$ , flow is not choked, and  $P$  is equated to  $P_b$  in Eq. (23-108) to obtain the unchoked mass flux.

A relief rate formula for two-phase flow similar to Eq. (23-102) for gas can be written as

$$W = K_d K_b A G \quad (23-111)$$

For the boiling-liquid system,  $\omega$  is calculated from Eq. (23-104) or Eq. (23-105), while for a gas-generating system,  $\omega$  is evaluated from Eq. (23-106).

For **pipe flow**, HEM requires solution of the equations of conservation of mass, energy, and momentum. The momentum equation is in differential form, which requires partitioning the pipe into segments and carrying out numerical integration. For constant-diameter pipe, these conservation equations are as follows:

Mass:

$$G = \text{constant} \quad (23-112)$$

Energy:

$$h_0 = h + \frac{G^2 v^2}{2} \quad (23-113)$$

Momentum:

$$v \, dP + G^2 \left( v \, dv + \frac{4fv^2 \, dL}{2D} \right) + g \cos \theta \, dL = 0 \quad (23-114)$$

where  $h_0$  is enthalpy at stagnation (J/kg),  $h$  is enthalpy (J/kg),  $v$  is fluid specific volume,  $f$  is Fanning friction factor,  $L$  is flow length (m),  $g$  is acceleration due to gravity, and  $\theta$  is angle of inclination from vertical.

Equation (23-114), the momentum equation, can be solved more conveniently by rewriting it and solving it numerically

$$\Delta L = - \frac{\bar{v} \Delta P + G^2 v \Delta v}{(2f/D)G^2 v^2 + g \cos \theta} \quad (23-115)$$

where  $\bar{v}$  is the average specific volume in the pressure increment  $\Delta P$  and  $\Delta v$  is the incremental specific volume over  $\Delta P$ .

In the numerical integration of Eq. (23-115) for a given pipe length  $L$ , the following steps are suggested (note that detailed thermodynamic properties are required also):

1. Either  $G$  is known or guessed.
2. Increments of pressure are taken from the initial to the final pressure.
3. Both  $\bar{v}$  and  $\Delta v$  are obtained for each increment for a constant stagnation enthalpy process satisfying Eq. (23-113).
4. For each  $\Delta P$  taken,  $\Delta L$  is computed from Eq. (23-115).
5. Total length of pipe  $L$  is  $\Sigma \Delta L$ .
6. If  $\Delta L$  is negative, then  $\Delta P$  is too large.
7. A critical flow condition corresponds to  $\Delta L = 0$ , and the final pressure corresponds to choked pressure.
8. If  $\Sigma \Delta L > L$ , then  $G$  was guessed too small, and steps 1 through 7 are repeated with a larger  $G$ . If  $\Sigma \Delta L < L$ , then  $G$  was guessed too large; steps 1 through 7 are repeated with a smaller  $G$ .
9. A converged solution is obtained when  $\Sigma \Delta L = L$  to within a given tolerance.

The above calculations can be simplified somewhat by ignoring the kinetic energy term in the energy equation, Eq. (23-113), and simply basing calculations on an isenthalpic flash. Thus a  $P$ - $v$  relation can be obtained from such flash calculations prior to performing the above iteration steps. In the special case of turbulent pipe flow horizontal discharge ( $\cos \theta = 0$ ), Eq. (23-114) can be integrated based on the omega  $P$ - $v$  relation to yield [Leung and Grolmes, "The Discharge of Two-Phase Flashing Flow in a Horizontal Duct," *AICHE J.* 33(3), pp. 524–527, 1987; also errata, 34(6), p. 1030, 1988]

$$4f \frac{L}{D} = \frac{2}{G^2} \left[ \frac{\eta_1 - \eta_2}{1 - \omega} + \frac{\omega}{(1 - \omega)^2} \ln \frac{(1 - \omega)\eta_2 + \omega}{(1 - \omega)\eta_1 + \omega} \right] - 2 \ln \left[ \frac{(1 - \omega)\eta_2 + \omega}{(1 - \omega)\eta_1 + \omega} \left( \frac{\eta_1}{\eta_2} \right) \right] \quad (23-116)$$

where  $\eta_1 \equiv P_1/P_0$ ,  $\eta_2 \equiv P_2/P_0$ ,  $G^* \equiv G/\sqrt{P_0/v_0}$ ,  $P_1$  is the absolute static pressure at the inlet of the pipe ( $\text{N/m}^2$ ),  $P_2$  is the absolute static pressure at the outlet of the pipe ( $\text{N/m}^2$ ), and  $P_0$  is the reference pressure typically associated with the stagnation pressure in the upstream equipment. The choking criterion at pipe exit takes the form

$$G_c^* = \frac{\eta_{2c}}{\sqrt{\omega}} \quad (23-117)$$

where subscript  $c$  denotes choking. The integrated momentum equation, Eq. (23-116), yields the pressure drop  $P_1 - P_2$  in the pipe implicitly as a function of  $\omega$ ,  $4fL/D$ , and  $G$ . For the case of a pipe discharge from a vessel, the inlet acceleration pressure drop  $P_0 - P_1$  is given by Eq. (23-108) above with  $P/P_0$  being  $P_1/P_0$  or  $\eta_1$ . Essentially the inlet pipe section is treated as an ideal nozzle, and any irreversible loss due to sharp entrance effect is included in the overall  $4fL/D$  term. Likewise, the velocity head loss associated with bends (elbows) is to be included in the  $4fL/D$  term as well. For high-velocity, two-phase discharge, an average  $f$  value of 0.005 has been used in most applications (Wallis, 1969).

Choked pipe exit:  $\eta_{2c} > \eta_b$  or  $P_{2c} > P_b$ . Equations (23-109), (23-116), and (23-117) are used to solve for  $G_c^*$ ,  $\eta_{1c}$ , and  $\eta_{2c}$  (likewise, for  $G_c$ ,  $P_{1c}$ , and  $P_{2c}$ ) for a given  $4fL/D$  and  $\omega$  value.

Unchoked pipe exit:  $\eta_{2c} < \eta_b$  or  $P_{2c} < P_b$ . Equation (23-116) does not apply. With  $\eta_2 = \eta_b$  (or  $P_2 = P_b$ ) for an unchoked exit, only Eqs. (23-108) and (23-116) are needed to solve for  $G^*$  and  $\eta_1$  (likewise, for  $G$  and  $P_1$ ). Under most situations, it suffices to set  $\eta_1 = 1$  and to solve for  $G^*$  readily by rearranging Eq. (23-116).

This method has been extended to inclined pipe discharge [Leung and Epstein, "The Discharge of Two-Phase Flashing Flow from an Inclined Duct," *Trans. ASME J. Heat Transfer* 112 (May), pp. 524–528, 1990], which together with some useful design charts is presented in the earlier subsection "Discharge Rates from Punctured Lines and Vessels."

## EMERGENCY RELIEF DEVICE EFFLUENT COLLECTION AND HANDLING

**Introduction** In determining the disposal of an effluent vent stream from an emergency relief device (safety valve or rupture disk), a number of factors must be considered, such as

1. Is the stream single-phase (gas or vapor) or multiphase (vapor-liquid or vapor-liquid-solid)?
2. Is the stream flammable or prone to deflagration?
3. Is the stream toxic?
4. Is the stream corrosive to equipment or personnel?

Some vent streams, such as light hydrocarbons, can be discharged directly to the atmosphere even though they are flammable and explosive. This can be done because the high-velocity discharge entrains sufficient air to lower the hydrocarbon concentration below the lower explosive limit (API RP 521, 2007). Toxic vapors must be sent to a flare or scrubber to render them harmless. Multiphase streams, such as those discharged as a result of a runaway reaction, e.g., must first be routed to separation or containment equipment before final discharge to a flare, a scrubber, or a quench pool tank.

This discussion is organized into three major areas: types of equipment, criteria employed in the selection of equipment, and sizing and design of the equipment.

**Types of Equipment** Equipment for handling emergency relief discharge streams can be divided into two classes:

1. Vapor/gas/solid-liquid separators
2. Final vapor/gas control or destruction equipment

The two most commonly used types of vapor/gas-liquid separators are

- Gravity separators—horizontal and vertical (also called blowdown drums, knockout drums, or catch tanks)
  - Emergency cyclone separators
- The most commonly used types of final vapor/gas control or destruction equipment are
- Quench pools/catch tanks and quench towers
  - Emergency flare systems
  - Emergency scrubbers (absorbers)

**Gravity Separators** Three types of gravity separators are commonly used in the chemical process industries (CPI): horizontal blowdown drum/catch tank, vertical blowdown drum/catch tank, and multi-reactor knockout drum/catch tank.

**Horizontal blowdown drum/catch tank** This type of drum, shown in Fig. 23-49, combines both the vapor-liquid separation and holdup functions in one vessel. Horizontal drums are commonly used where space is plentiful. The two-phase mixture usually enters at one end, and the vapor exits at the other end. To overcome reentrainment of liquid droplets, due to high inlet velocities, various devices and piping arrangements are used to provide a more uniform distribution of vapor-liquid mixtures into the separator, as shown in Fig. 23-50. For two-phase streams with very high vapor flow rates, inlets may be provided at each end, with the vapor outlet at the center of the drum, thus minimizing vapor velocities at the inlet and aiding vapor-liquid separation.

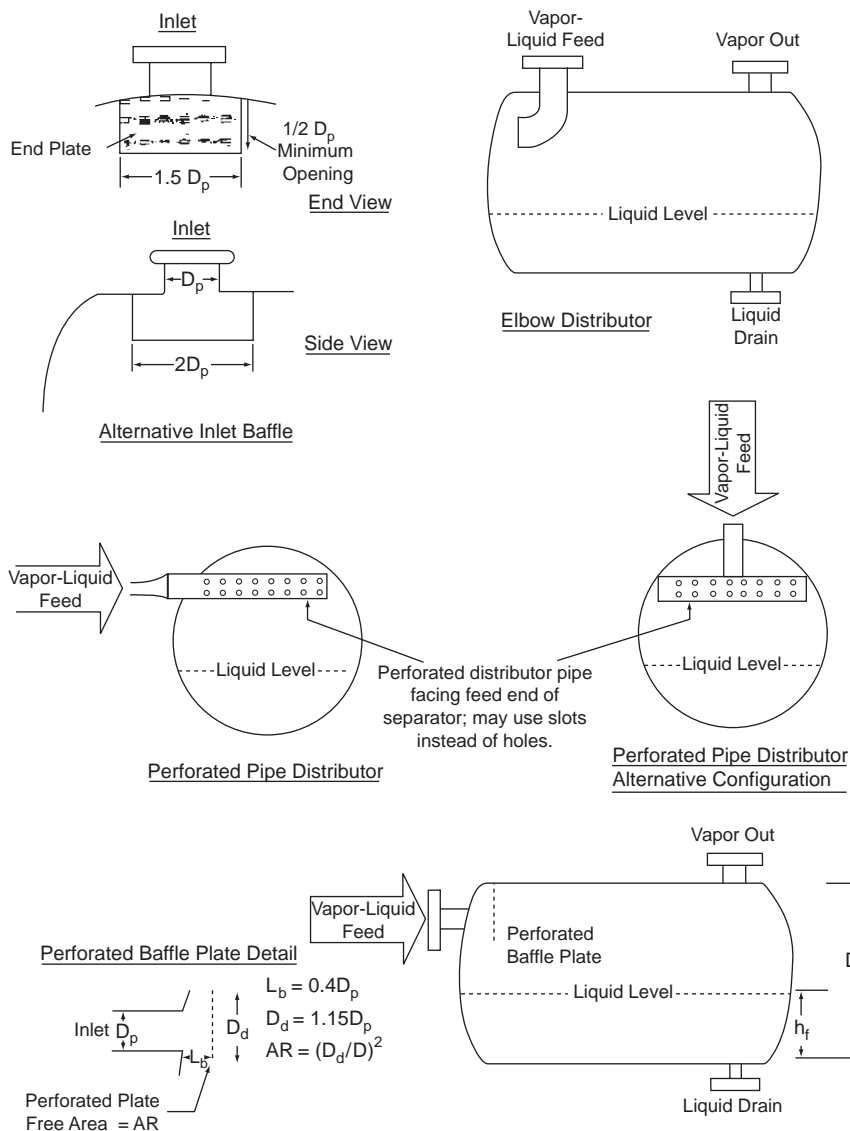

FIG. 23-49 Horizontal blowdown drum/catch tank.

**FIG. 23-50** Feed distributor devices for horizontal blowdown drums/catch tanks. (Guidelines for Pressure Relief and Effluent Handling Systems, *Center for Chemical Process Safety (CCPS) of the American Institute of Chemical Engineers (AIChE)*; copyright 1988 AIChE and reproduced with permission.)

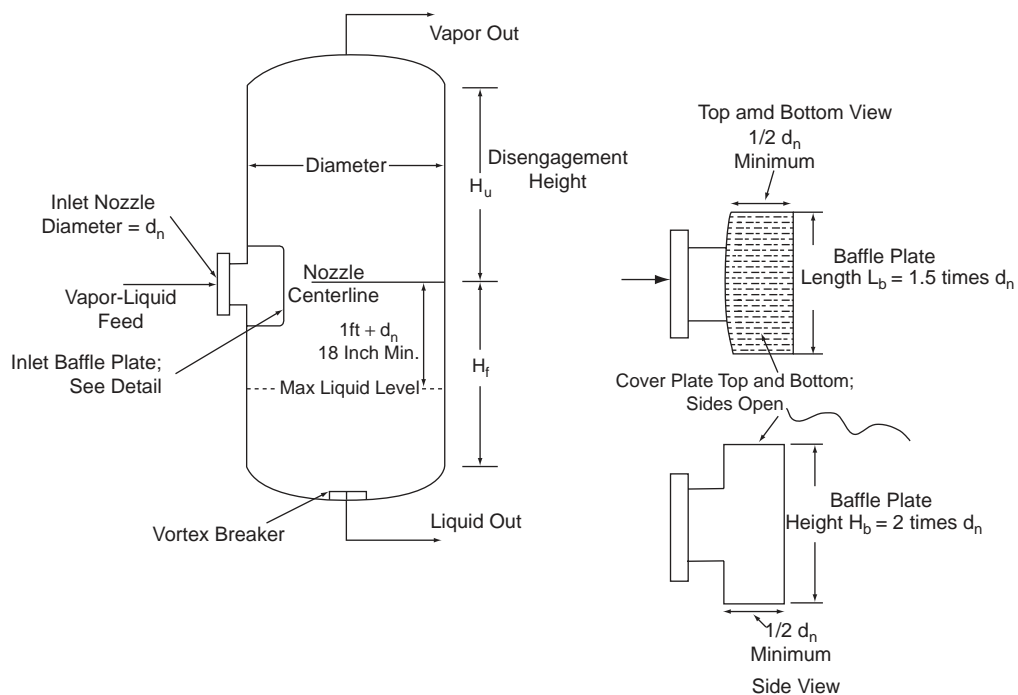

**Vertical blowdown drum/catch tank** This type of drum, shown in Fig. 23-51, performs the same function and operates on similar principles as horizontal separators. These separators are usually used where horizontal space is limited. The two-phase mixture enters the vessel via a nozzle on the vertical shell and is distributed by an inlet baffle chamber.

**Multireactor knockout drum/catch tank** This interesting system is sometimes used as the containment vessel for a series of closely spaced reactors (Speechny et al., "Principles of Total Containment System Design," presented at I.Chem.E. North West Branch Meeting, 1979).

**Emergency Cyclone Separators** Two types of emergency cyclone separators are commonly used, those with a separate catch tank and those with a catch tank integral with the cyclone section.

**Cyclone separator with separate catch tank** This type of blowdown system, shown in Figs. 23-52 and 23-53, is frequently used in chemical plants where plot plan space is limited. The cyclone performs the vapor-liquid separation, while the catch tank accumulates the liquid from the cyclone. This arrangement allows location of the cyclone knockout drum close to the reactor so that the length of the relief device discharge line can be minimized. The cyclone has internals, vital to its proper operation, which are discussed in the following subsections.

**Cyclone separator with integral catch tank** This type of containment system, depicted in Fig. 23-54, is similar to the aforementioned type, except that the knockout drum and catch tank are combined in one vessel shell. This design is used when the vapor rate is quite high so that the knockout drum diameter is large.

**FIG. 23-51** Vertical blowdown drum/catch tank. (Guidelines for Pressure Relief and Effluent Handling Systems, *Center for Chemical Process Safety (CCPS) of the American Institute of Chemical Engineers (AIChE)*; copyright 1988 AIChE and reproduced with permission.).

**FIG. 23-52** Cyclone separator with separate liquid catch tank.

**FIG. 23-53** Cyclone separator design details. (Guidelines for Pressure Relief and Effluent Handling Systems, *Center for Chemical Process Safety (CCPS) of the American Institute of Chemical Engineers (AIChE)*; copyright 1988 AIChE and reproduced with permission.)

**Quench Pools/Catch Tanks and Quench Towers** Two types of quench systems are commonly used: the quench pool/catch tank (also called passive scrubber) and quench tower.

**Quench pool/catch tank** This type of system, as shown in Fig. 23-55, is used to condense, cool, react with, and/or collect a mixture of liquid and vapors discharging from a relief device by passing them through a pool of liquid in a vessel. Feed vapor and liquid (if present) are sparged into the pool of cool liquid, where the vapors are condensed and the liquid is cooled. If the feed materials are miscible with the pool liquid, they mix with and are diluted by the pool liquid; if not, the condensate, feed liquid, and pool liquid separate into layers after the emergency relief event is over. The condensed vapors, feed liquid, and quench liquid are contained in the vessel until they are sent to final disposal.

Quench pools can be used for the neutralization or killing of reactive materials. A chemical reaction can be quenched by the cooling

effect in the pool, by the dilution effect if the reaction mass is miscible with the pool liquid, or by a killing or neutralizing agent added to the quench liquid. For example, discharge of chlorine or acid mixtures can be neutralized by adding sodium hydroxide to the quench liquid. However, systems involving slow to moderate reaction rates usually require more than one contacting stage, and a quench pool (equal to one stage only) may not be adequate to completely neutralize or kill the reactant in the entering relief device effluent stream. In this case, a multiple-stage emergency scrubber will be needed.

Depending on the relief stream components (with or without non-condensable gases) and quenching efficiency, this arrangement often obviates the need for a subsequent scrubber and/or flare stack. The design of the quencher arm is critical to efficient condensation and avoidance of water hammer. Figure 23-55 is the more conventional passive type quench pool used in the chemical and nuclear industry.

FIG. 23-54 Cyclone separator with integral catch tank.

**Quench tower** The type shown in Fig. 23-56, with a superimposed baffle plate section, is often used when complete condensation of the incoming vapors is not required. The exiting vapors are usually cooled to 150 to 200°F in the baffle plate section. This type is often used in petroleum refineries.

**Emergency Flare Systems** Single-phase effluent streams (gases or vapors) from pressure relief devices are often sent directly to emergency flares. The vapor/gas streams from gas-liquid separators are also often sent to emergency flares. Emergency flares are similar in design to normal process flares (continuous flaring), but they are only used to handle emergency releases (intermittent operation).

Flares can be grouped into two major categories, i.e., vertical and horizontal.

**Vertical flares** These are single-burner combusters generally oriented to fire upward. The discharge point is in an elevated position relative to the surrounding grade and/or nearby equipment. Three types of support methods are used for vertical flares:

- **Self-supported.** A mechanically and structurally designed riser supports the flame burner.
- **Guyed.** An elevated flare with the riser is supported by cables. Cables are attached to the flare riser at one or more elevations to limit the deflection of the structure. The cables (guy-wires) are typically positioned in a triangular plan to provide strong support.
- **Derrick supported.** Support is provided by a steel trussed structure that supports one or more flare risers.

The main components of an elevated flare system are the flare burner with or without smoke suppression capability, pilot(s), pilot igniter(s), support structure, and piping. A number of optional features are available, such as pilot flame detectors; air seals (buoyancy or

velocity type); knockout drum; flame/detonation arrester; liquid seal; smoke suppression control system; blower(s); flow, composition, heat content, or video monitoring; ladders (caged or with safety-climbing system) and platforms; davit for tip removal; aircraft warning lights and painting; radiation heat shields; and rain shields. Detailed information about these components can be found in API STD 537.

Smokeless flaring is required by law in the United States (40 CFR 60.18, Chap. 1) for normal process flares (continuous flaring). However, smokeless flaring is not required by the EPA for emergency flaring, but local conditions and regulations may require smokeless flaring.

Air seals (also called purge reduction or gas seals) are often recommended to prevent air from entering the stack, which could possibly cause flashbacks and explosions. More information about air seals can be found in API RP 521 (2007) and the AIChE-CCPS book *Guidelines for Pressure Relief and Effluent Handling Systems*.

**Horizontal flares** A horizontal flare can be either an enclosed ground flare or an open field ground flare (also called a matrix flare).

**Enclosed ground flares** are most commonly used as a supplement to an elevated flare on the same relief system. The primary reason for an enclosed ground flare is to reduce the visual impact of flared gas combustion on a nearby community. They are often used when it is desirable that all or part of a flare load be disposed of in a way that causes the minimum of disturbance to the immediate locality. They offer many advantages in comparison to elevated flares; there is no smoke, no visible flame, no odor, no objectionable noise, and no thermal radiation (heat shield) problems. Enclosed ground flares are typically used for normal process flow (continuous) flaring, but with recent technical advances they are now also used for emergency flaring (AIChE-CCPS, 1998).

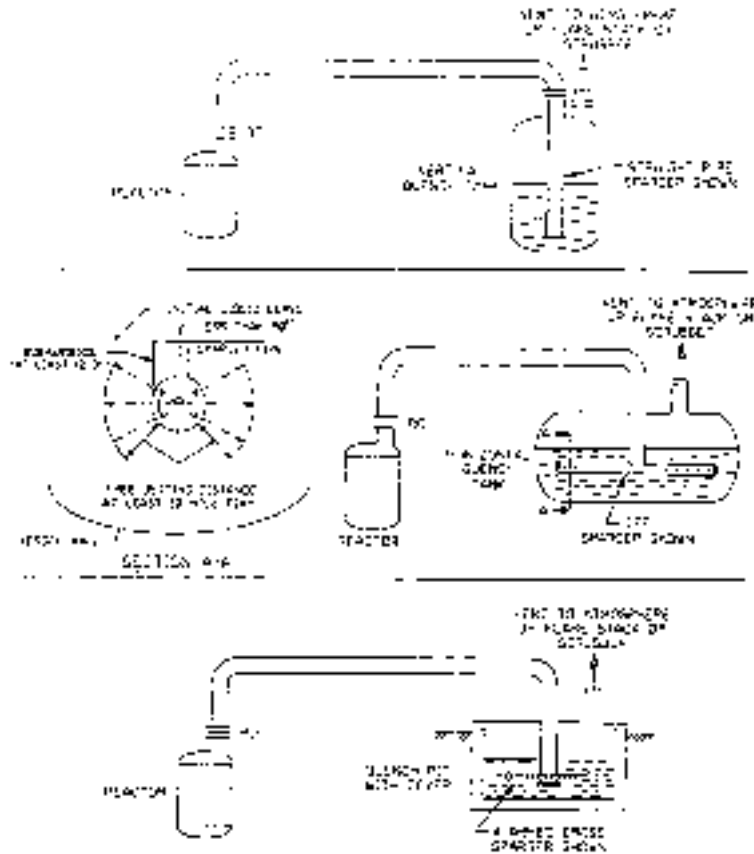

FIG. 23-55 Quench tank/catch tank.

Enclosed ground flares burn the effluent gas in multiple specially designed multitip burners placed as near to the ground as practicable to ensure good operation. The resulting flames are hidden from sight by a surrounding wall or chamber. The top of the chamber is open to the atmosphere, and allowance is made in the bottom of the chamber to permit ingress of air for combustion. Overall heights can vary according to the needs of the specific location. In some locations, a low profile of perhaps 10 m may be mandated, while in others an elevated discharge may be needed to ensure a satisfactory downwind trajectory for the flue gases. It is common for the chamber to be surrounded by a wind fence to modify the effect of crosswinds on the combustion process and to prevent unauthorized access.

An enclosed ground flare system has a number of key components: combustion chamber, burners, piping system, wind fence, and operational and safety controls. More details about enclosed ground flare system components are given in API STD 537.

Enclosed ground flares can be used to burn toxic gases, but since any noncombusted release would be near the ground, special safety dispersion systems and more stringent monitoring and control instrumentation are usually provided in this application.

There is a practical economical limit to the size of enclosed ground flares. If the maximum effluent relief rate exceeds 100 tons/h, the feasibility of an enclosed ground flare becomes questionable, and at 500 tons/h, it is impractical (AIChE-CCPS, 1998).

**Open field ground flares** (also called **matrix flares**) are sometimes used in lieu of elevated flares, most commonly, although not exclusively, in remote locations with relatively low population density.

A primary reason for use of an open field ground (matrix) flare is to reduce the visual impact of flared gas combustion in the manner of an enclosed ground flare. The open field ground (matrix) flare, however, has a significantly larger capacity than could be practically handled in a furnacelike structure, and the visual shielding is provided by tall fencing located some distance away from the burners themselves so that the fence encloses a small "field."

An open field (matrix) ground flare consists of a number of staged multiburners mounted on a series of horizontal pipes, arranged in manifolds, in a large field or pit. Smokeless or nonsmokeless flaring can be provided. The main structural and physical design issues are concerned with protecting the piping and manifolds inside the flare field from the effects of high radiant heat loads, while still permitting normal thermal expansions. More information about ground flare components is given in API STD 537.

**Emergency Scrubbers (Absorbers)** Emergency relief effluent streams are often sent to scrubbers (also called absorbers, columns, or towers) for final disposal by absorption of the gas into a solvent. Some gases or vapors can be removed by physical absorption. Other gases or vapors can be removed by chemical absorption (reaction of the vent gas/vapor into a liquid that reacts with it).

A typical emergency scrubber system consists of a scrubbing column (often filled with packing), recirculating liquid pumps, solvent cooler, and in some cases (where the entering effluent gas/vapor is at a low pressure) exhaust blowers (see Fig. 23-57). Redundant equipment and instrumentation is usually provided to ensure reliable scrubber operation at all times.

FIG. 23-56 Quench tank with direct-contact baffle tray section.

**Equipment Selection Criteria and Guidelines** A number of factors should be considered to determine when to select which type of vapor/gas/solid-liquid separator (blowdown drum or cyclone separator) to handle a multiphase stream from a relief device, and which final control or destruction equipment (emergency flare, emergency scrubber, or quench pool/catch tank) should be selected. These factors include the plot plan space available, the operating limitations of each type, and the physicochemical properties of the stream.

The selection of vapor/gas/solid-liquid separators and final control and destruction equipment can be helped by considering the advantages and disadvantages of each, as given below.

#### **Gravity Separators (Horizontal and Vertical Drums/Catch Tanks)**

Advantages:

- History of good performance.
  - Passive.
  - Excellent turndown up to the maximum design flow; lower vapor flow improves separation effectiveness.
  - Low pressure drop.
  - Can handle high liquid loading and provide large holdup of liquid.
  - Can be combined with secondary vapor-liquid separator such as vane impingement type.
  - Can handle high-viscosity liquids.
  - Moderate cost.
- Disadvantages:
- May be large.
  - Cannot economically remove low-density (e.g., light hydrocarbon) droplets smaller than about 150  $\mu\text{m}$ .
  - Cannot handle stable foams.
  - Reacting liquids may continue to react in separator.

#### **Cyclones**

Advantages:

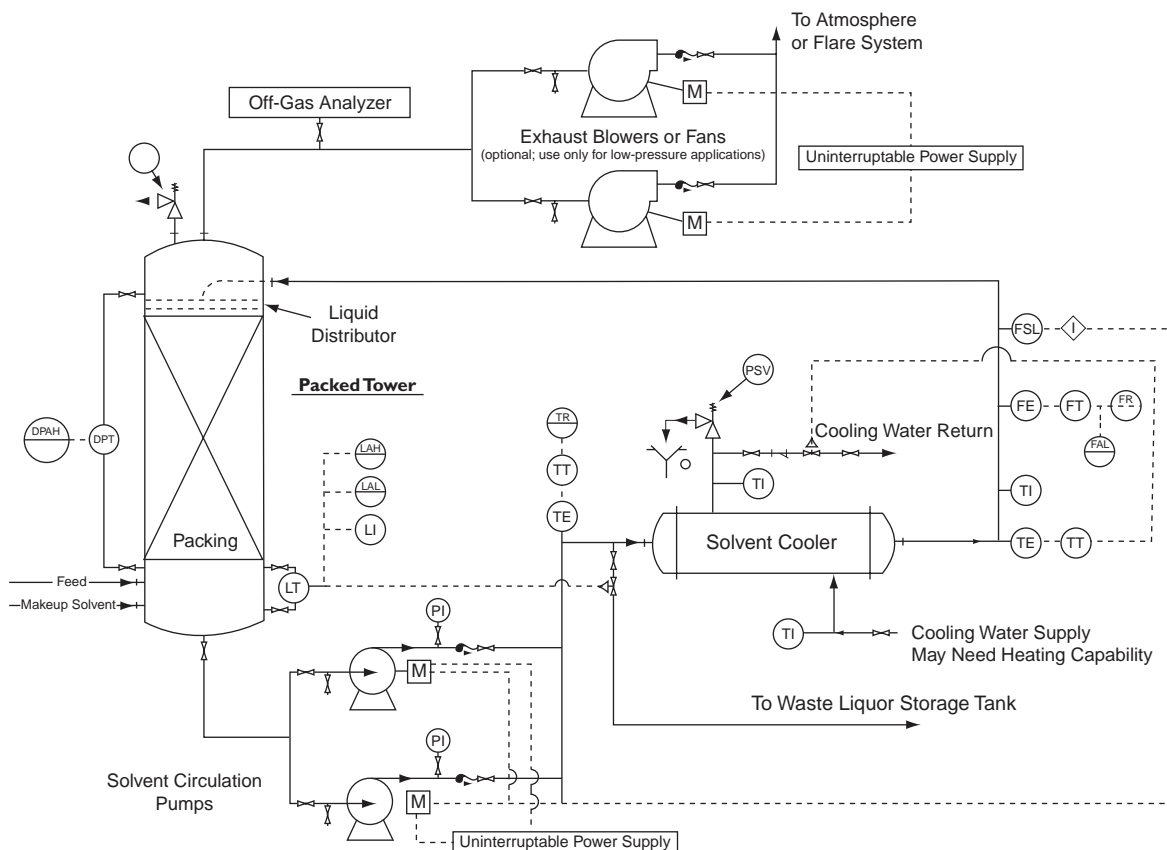

- Can remove over 99 percent above 20- $\mu\text{m}$  droplet diameter in high liquid-loading situations.

- Some designs able to handle foamy liquids under some conditions.
  - Passive.
  - May be able to handle streams containing solids or with fouling tendencies.
  - Relatively low capital cost.
- Disadvantages:
- Performance not as well defined for emergency services as normal process cyclones.
  - Little data on handling foamy or high-viscosity mixtures.
  - May require higher pressure drop than gravity separators.

#### **Quench Pool Tanks/Catch Tanks**

Advantages:

- Passive, but must have system to verify proper liquid level, and composition if pool liquid is used as a neutralizing or kill liquid.
  - Can handle two-phase, foamy, and high-viscosity liquids.
  - Can handle high-flow-rate discharges.
  - Can handle high liquid loading with special sparger design.
  - Can contain reaction-stopping or -neutralizing chemicals and antifoam agents.
  - Complete containment possible at low levels of noncondensables.
  - Can use variety of quench liquids.
- Disadvantages:
- Pilot-plant demonstration or scale-up test possibly needed.
  - Requires sufficient discharge pressure to provide adequate pressure drop (at least 10 psig) across sparger and to overcome static head of liquid in pool.
  - Sparger piping to be supported to control vibration and the suddenly applied load from the relief discharge.
  - Some proven sparger designs are proprietary.
  - May not be suitable for systems with slow to moderate reaction rates when used as an absorber.
  - If vented, entrainment and vapor may be carried out of the vessel.

**FIG. 23-57** Schematic of an emergency scrubber (absorber) system. (Guidelines for Pressure Relief and Effluent Handling Systems, *Center for Chemical Process Safety (CCPS) of the American Institute of Chemical Engineers (AIChE)*; copyright 1988 AIChE and reproduced with permission.)

- Noncondensables in the feed will lower recovery efficiency, and need to be vented.
- May require large pool to handle lower-boiling materials.

#### **Emergency Flares**

##### Advantages:

- Can destroy over 98 percent of combustibles.
- Experimental tests not required for most chemicals.
- Commercially proven technology.
- Very reliable—onstream over 99 percent.
- Good turndown ratio.
- Smokeless operation not needed for emergency flares (only required for continuous flares).
- No generation of appreciable liquid waste as would be the case for a quench pool or an emergency scrubber, but knockout drum required upstream of the flare to remove liquids and any condensate.
- May be used as final step after other control equipment, e.g., emergency scrubber or quench pool.

##### Disadvantages:

- May not be suitable for some corrosive chemicals (e.g., most chlorine-containing compounds).
- May be subject to flameout.
- Required minimum heating value of 300 Btu/SCF for nonassisted flares, or 200 Btu/SCF for assisted flares.
- Not passive; require continuous pilot fuel, electricity, oxygen analyzers for collection headers, and instrumentation.

- Require backup systems to monitor flame and provide pilot burning.
- Care needed not to feed foams or liquids into the flare stack.
- Because of maintenance of flare tip on elevated flares (and even some open ground and enclosed ground flares), crane or helicopter required possibly for access. Connection often needed for backup flare system, i.e., portable trailer flare or other temporary flare.

- Elevated flares with excessive light, noise, or odors a possible public nuisance in some situations and locales.

#### **Emergency Scrubbers**

##### Advantages:

- Sound basis for technology.
- High turndown ratio at constant scrubbing liquid flow rate.
- Countercurrent operation that can attain high absorption (removal) efficiency and low outlet concentration of solute.
- Can handle two-phase mixtures.
- May be able to handle unstable foams (to be confirmed by testing).
- Some types of scrubbers that can handle fouling streams, and baffle trays that can handle fouling and solids-containing streams.
- Can be used for neutralization of reactive materials.
- Generally used only for gas/vapor feed, but can handle liquid by use of a separator section in the bottom of the tower.

##### Disadvantages:

- Possible need for spent solvent to be treated or disposed of after the emergency release.

- Not passive. Utilities and process control instrumentation must be available at all times, and must have a sufficient and reliable supply of fresh solvent for the expected duration of the emergency.
- May need large diameter to avoid flooding.
- Possible restriction of tray towers to nonfouling materials that are free of suspended solids.
- May need continuous flow of scrubbing solvent for the scrubber to be effective at the start of the effluent flow.
- *Guidelines for Pressure Relief and Effluent Handling Systems* (AIChE-CCPS, 1998) contains more information about selection criteria and factors that affect them.

**Sizing and Design of Equipment** This subsection presents sizing methods and design criteria for the design of vapor/gas/solid-liquid separators for normal vapor-liquid systems (low-viscosity and nonfoamy or unstable foams). They are not applicable usually to high-viscosity (newtonian and nonnewtonian) liquids and/or systems that exhibit surface-active foaming behavior, as insufficient information is available at present relating to the separation efficiency for these types of equipment. Design information is also presented for quench pool tanks which usually can handle high-viscosity liquids as well as stable foams, and for final vapor/gas control or destruction equipment.

**Vapor-Liquid Gravity Separator Design Fundamentals** The critical factors in the performance of a horizontal separator are the vapor residence time and the settling rate of the liquid droplets. However, two other factors enter into the design—the vapor velocity must be limited to avoid liquid entrainment, and there must be sufficient freeboard within the vessel to allow for a feed distributor. For vertical separators, the design is based on a vapor velocity that must be less than the settling velocity of the smallest droplet that is to be collected, with due allowance for turbulence and maldistribution of the feed. The vapor residence time is a function of the vapor flow rate (mass), vapor density, and volume of vapor space in the separator, based on the following:

- The vapor flow rate (mass) is the sum of the vapor feed to the separator and any vapor generated by flashing of the liquid as the feed enters the separator.
- The vapor density depends on the compositions of the vapor fed and the vapor generated, and the pressure and temperature within the separator. The pressure in the separator is essentially the sum of the pressure drop from the outlet of the separator to the ultimate disposal point of the effluent and the pressure at the downstream discharge location (e.g., the atmosphere).
- The vapor volume is the total volume of the separator minus the volume of the liquid collected; and the volume of liquid is the volume collected (separated) from the feed minus the volume of liquid flashed when the static pressure decreases as the flow rate declines. The maximum volume of liquid collected is also a function of pressure—a greater volume is collected at higher pressure, and time.

**Horizontal Blowdown Drum/Catch Tank** (See Fig. 23-49.) The two main criteria used in sizing horizontal blowdown drums or catch tanks are as follows:

1. The diameter must be sufficient to provide good vapor-liquid separation.
2. The total volume must be sufficient to hold the estimated amount of liquid carryover from the reactor or process vessel. For a foamy discharge, the holding volume should be greater than the reactor or process vessel volume (to be discussed below).

The recommended method is from *Guidelines for Pressure Relief and Effluent Handling Systems* (AIChE-CCPS, 1998). It is an improvement over the method presented in the 7th edition of this Handbook. The procedure involves calculating a terminal velocity for a selected droplet size, then providing enough residence time in the vapor space to allow the droplets to fall from the top of the vessel to the level of liquid collected. Also, the vapor velocity in the separator must not exceed the value above which liquid may be entrained from the liquid surface in the separator. The tank is treated as a simple horizontal cylinder, neglecting the volume of liquid in the heads.

Other approaches for sizing a horizontal separator (blowdown drum) are given in *Guidelines for Pressure Relief and Effluent Handling Systems* (AIChE-CCPS, 1998) and API RP 521 (2007).

**Vertical Blowdown Drum/Catch Tank** (See Fig. 23-51.) Some of the basic equations used for sizing horizontal separators can be applied to vertical separators; however, the superficial vapor velocity for vertical separators is based on the total vessel cross-sectional area, and the vapor velocity must be less than the terminal settling velocity for the droplet size selected as the basis of design.

The recommended design procedure is also from *Guidelines for Pressure Relief and Effluent Handling Systems* (AIChE-CCPS, 1998). As with a horizontal separator, the assumed value of  $K$  is expected to be suitable for most vertical separators in emergency relief services. However, if it is necessary to remove droplets smaller than 300 to 600  $\mu\text{m}$ , then lower values of  $K$  should be used.

**Multireactor Knockout Drum/Catch Tank** The area needed for vapor disengaging is calculated by the equations given earlier in the section on horizontal blowdown drums. The diameter and length (or height) are determined by considering a number of factors:

1. The length should be sufficient to extend beyond the locations of the reactors discharging into the vessel so as to simplify discharge pipe runs (for a horizontal vessel).
2. The height should not greatly exceed the height of the building (for vertical vessels).
3. The diameter should be sufficient to allow attenuation of the shock wave leaving the deflector plate.
4. The diameter should be sufficient to allow installation of the pipes and deflector plates in such a way as not to interfere directly with one another (particularly important for vertical vessels).
5. The cost of pressure vessels increases as the diameter increases.
6. An upper limit to the diameter is set by the need to transport complete cylindrical sections from the manufacturer to the site.
7. The volume of liquid in the reactor or reactors (assuming more than one vents at the same time) must be determined.

**Mechanical Design Considerations** The paper by Speechly et al. ("Principles of Total Containment System Design," presented at I. Chem. E. Northwestern Branch Meeting, 1979) discusses a number of pertinent design features:

1. Each vent device discharge pipe is extended into the vessel, and its end is fitted with a deflector device. This disperses the jet stream of solids (catalyst) and liquids discharged and dissipates this force, which should otherwise be exerted on the vessel wall immediately opposite.

2. The deflector device (baffle plate) must be carefully designed as described by Woods (*Proc. Inst. Mech. Engrs.* 180, Part 3J: 245–259, 1965–1966).

3. Isolate the catch tank from both reaction loads and forces generated by thermal expansion of the pipes; the pipes can be designed to enter the vessel through a sliding gland. Depending on layout, vessels that tend to have shorter, stiffer pipes between the building and the vessel may also require flexible bellows to be incorporated in the pipes.

4. There are usually several reactors linked to a single catch tank. To ensure that rupture of a disk on one reactor does not affect the others, each reactor is fitted with a double-rupture disk assembly. The use of double-rupture disks in this application requires installation of a leak detection device in the space between the two disks.

**Gravity Separator Safety Considerations and Features** A pressure relief device may be required on vapor-liquid gravity separators, based on the following assumptions:

- External fire exposure, if the vapor outlet is inadequately sized for fire relief.
- The vessel outlets could be closed.
- A chemical reaction could continue in the knockout drum/catch tank.

The pressure relief device should be evaluated and sized in accordance with the latest industry standards (i.e., DIERS, API, NFPA). An open passage (nozzle or line) from the separator to the atmosphere may be considered as the pressure relief device provided that it meets the relieving capacity requirements of the ASME Boiler and Pressure Vessel Code (BPVC).

Freeze protection is not normally provided in separators intended solely for emergency release service; however, occasionally, coils or a

jacket are used to keep high-viscosity liquids flowable, or to boil off volatile components. If internal coils or a heating jacket is used, it should be recognized that the source of heat might initiate a chemical reaction or increase its rate. Internal heating coils should be

- Designed for complete drainage.
- Provided with block valves to shut off the source of heat.
- Designed with a generous corrosion allowance.
- Braced to withstand impingement by the relief effluent stream.

Also the calculated liquid level in the separator should be corrected for the volume of the internal coils, and a heel of solvent might be retained in the separator to prevent freezing or to dissolve any components that can solidify or freeze.

**Gravity Separator Vessel Design and Instrumentation** Some of or all the following features might be appropriate in selected situations [also see API RP 521(2007)]:

- Liquid level indicator.
- High and low level alarms.
- Temperature indicator (with high-temperature alarm if deemed necessary).
- Pressure gauge.
- Pressure relief device.
- Manhole(s) for tank entry and cleaning.
- Pump for transferring the accumulated liquid to subsequent rework, recovery, or disposal.
- Antivortex baffle above the liquid outlet to the pump.
- Bracing of wall stiffeners to allow for possible "jet force" impingement on the vessel wall, and for intermittent buffeting and vibration if two-phase slug flow can occur.

For separators that normally operate at about atmospheric pressure, consider designing the vessel for 50 or 75 psig minimum MAWP to avoid vessel damage by an internal deflagration. For higher normal operating pressures, the design basis should be adjusted accordingly, consistent with the ASME BPVC, NFPA 68, and NFPA 69.

It should be realized that the separator may not be used for long periods, and the process control instrumentation and auxiliaries must receive regular inspection, testing, and maintenance.

**Emergency Cyclone Separators** Sizing of cyclone separators to handle unsteady-state discharge from emergency pressure relief devices is somewhat different from normal steady-state service (process cyclones). Emergency cyclones are designed usually for higher inlet velocity and pressure drop. Inlet velocity and cyclone pressure drop are limited only by the allowable backpressure on the pressure relief device. Emergency cyclone separator designs may allow some entrained mist or small droplets to leave the cyclone. This can be acceptable if the consequences of the release of the droplets are not significant.

Emergency cyclones often handle flashing vapor-liquid mixtures, and more vapor may be generated from flashing liquid because of the pressure drop in the cyclone; thus the mass flow rate of vapor leaving the cyclone is often greater than that entering. The cyclone size is determined by the outlet vapor volumetric flow rate. Since the discharge flow rate and ratio of vapor to liquid often vary, the cyclone design calculations should be made for conditions occurring at various times during the overpressure event.

**Cyclone separator with separate catch tank** (See Figs. 23-52 and 23-53.) The sizing of a cyclone knockout drum for emergency relief systems is somewhat different from that of a cyclone separator for normal process service for the following reasons:

1. In normal process service, the superficial vapor velocity at the inlet of tangential-entry vapor-liquid separators is limited to about 120 to 150 ft/s. Higher velocities may lead to
  - a. Excessive pressure drop in the separator and in the inlet piping.
  - b. Generation of fine mist in the inlet piping, which escapes collection in the separator.
2. Inlet velocity restrictions do not apply in the design of separators for emergency relief systems because
  - a. Pressure drop is usually not a penalty.
  - b. Escape of fine mist can usually be tolerated.

**Sizing procedure** The cyclone is sized by choosing a superficial  $F$  factor for the skirt in the range of 8.0 to 5.0 in USCS units (10 to 6 in

SI units). The higher value may be used for waterlike liquids; the lower value for liquids such as molasses. If design  $F$  factors exceed the range of 5 to 8, the liquid draining down the skirt is entrained and escapes with the vapor. These  $F$  factors were determined in small-scale lab experiments using water and a high-polymer solution as the test liquids. The high-polymer solution had a viscosity that was molasseslike, probably in the range of 1500 cP. There were no liquids of intermediate viscosity used in the tests.

The  $F$  factors of 5.0 and 8.0 are conservative in the opinion of the researcher who performed the experiments (private communication from E. I. duPont de Nemours Co., Inc., to the DIERS Project).

The sizing procedure is presented in *Guidelines for Pressure Relief and Effluent Handling Systems* (AIChE-CCPS, 1998). Figure 23-53 shows the dimensions of a cyclone separator designed in accordance with this procedure. If liquid is continuously drained from the cyclone to a separate accumulator, a vortex breaker and false bottom should be used (Fig. 23-53, view BB).

If the liquid contents of the vented vessel are to be retained in the separator for subsequent disposition, the holdup capacity may be increased by increasing the height of the vessel to increase the total volume by an amount equal to the vented liquid volume.

If the pressure drop is too high, it may be necessary to increase the inlet line size for a distance of about 3 to 5 diameters upstream of the cyclone.

A sizing method similar to the one recommended above is proposed by Schmid and Giesbrecht (2001), based on experimental work done at BASF in Germany.

**Cyclone separator with integral catch tank** (See Fig. 23-54.) The diameter of the knockout drum is calculated by the criteria given in the preceding subsection and Fig. 23-53. Since the liquid is also to be retained in the vessel, extend the shell height below the normal bottom tangent line to increase the total volume by an amount equal to the volume of the liquid carried over.

**Quench Tank** (See Figs. 23-55 and 23-56.) There is very little information in the open technical literature on the design of quench tanks in the chemical industry. Most of the information available deals with the design of quench tanks (also called suppression pools) for condensation of steam or steam-water mixtures from nuclear reactor safety valves. Information and criteria from quench tanks in the nuclear industry often can be used for the design of quench tanks in the chemical industry. *Guidelines for Pressure Relief and Effluent Handling Systems* (AIChE-CCPS, 1998) provides more information for chemical industry quench tank design. The following subsections summarize some of this information. Pertinent criteria for quench tank sizing and design are presented below:

**Operating pressure** There are three modes of operation of a quench tank: atmospheric pressure operation, nonvented operation, and controlled venting operation. Atmospheric operation is usually feasible when the effluent being emitted has a bubble point well above the maximum ambient temperature. A very small quantity of vapor escapes with the air that is displaced as the tank fills with the emergency discharge (typically about 0.2 percent of the reactor contents). Depending on the toxic or flammable properties of the vapor, the vent from the quench tank can be routed to the atmosphere or must be sent to a scrubber or flare.

In nonvented operation, no material is vented to the atmosphere, and this design is used when complete containment of the discharge is required. It is also used when the discharge mixture bubble point is close to or below the maximum ambient temperature and the concentration of noncondensable gas in the feed stream is very low. The tank design pressure is relatively high since the initial air in the tank is compressed by the rising liquid level, adding to the vapor pressure. The designer must take into consideration that the quench tank backpressure must be limited so as not to adversely affect the reactor relief system.

In controlled venting operation, the quench tank pressure is maintained at a desired level by a pressure controller/control valve system or pressure relief valve. This mode of operation is used when the discharge mixture bubble point is close to or below the maximum ambient temperature and it is desired to limit the maximum quench tank pressure.

**Quench liquid selection** The choice of the appropriate quench liquid depends on a number of factors. Water is usually the first quench liquid to consider. If water is selected as the quench liquid, the tank should be located indoors, if possible, to avoid freezing problems if the facility is in a cold climate. If the tank has to be located outdoors in a cold climate, the addition of antifreeze is preferable to heat-tracing the tank, since overheating of the tank can result from tracing, thus reducing its effectiveness.

If other quench liquids are required, the liquid should have as many of the following properties as possible: compatibility with the discharge effluent, low vapor pressure, high specific heat, low viscosity, low flammability, low freezing point, high thermal conductivity, immiscibility with the discharge effluent, low cost, and ready availability.

**Quench liquid quantity** A good discussion of the factors determining the quantity of quench liquid required is presented by CCPS (AIChE-CCPS, 1998).

When water is used as the quench medium and the effluent stream is a hydrocarbon or organic, separate liquid phases are often formed. In this case, heat transfer is the predominating mechanism during the quench. To achieve effective heat transfer, there must be a sufficient difference between the quench liquid temperature and the bubble point of the incoming effluent stream. The minimum temperature difference occurs at the end of the discharge, when the quench pool temperature is highest. A rule of thumb, from industry practice, is to allow a 10 to 20°C (18 to 36°F)  $\Delta T$ . For atmospheric tank operation, the final quench liquid temperature is then set 10 to 20°C (18 to 36°F) below the normal boiling point of the final quench pool mixture. For nonvented or controlled venting operation, the final boiling point is elevated, permitting a greater design temperature rise and the use of less quench liquid. Therefore, the quench pool final temperature must be set 10 to 20°C (18 to 36°F) lower than the saturated temperature of the discharge effluent at the design maximum quench tank pressure.

The minimum capacity of quench liquid can be estimated by a heat balance, given the final quench pool temperature, using an equation given by AIChE-CCPS (1998). An equation is also presented there that includes the heat of reaction. In some cases, an experiment is necessary to confirm that the reaction indeed stops in the quench pool. An equation is also presented for the heat balance needed to calculate the minimum amount of quench liquid when the feed contains noncondensable gases.

It is good practice to provide 10 to 20 percent more quench liquid than the minimum amount calculated.

**Quench tank volume** The total volume of the quench tank should be equal to the sum of the following volumes:

- Quench liquid required
- Liquid entering in the multiphase effluent stream
- Liquid condensed from vapors in entering effluent stream
- Freeboard for noncondensables (a minimum of 10 percent is recommended)

**Quench tank geometry** Quench tanks can have any of the following three types of geometry:

- Horizontal cylindrical vessel
- Vertical cylindrical vessel
- Concrete pit (usually rectangular)

Usually, the geometry is determined by space limitations. Both horizontal and vertical cylindrical vessels are designed as pressure vessels and for pressures up to 50 to 75 psig. An  $L/D$  ratio of 2 to 3 results in an economic design.

**Sparger design** The effluent stream should be discharged into the quench liquid by means of a sparger, which breaks it up into small jets to provide good heat and mass transfer. The sparger design must also incorporate the following capabilities:

- Maximize momentum-induced recirculation in the quench pool.
- Provide adequate flow area (cross section for pressure relief without imposing high backpressure).
- Minimize shock due to vapor bubble collapse.
- Minimize unbalanced momentum forces.

Figure 23-55 shows conventional quench tank sparger arrangements. As can be seen in this figure, the sparger can be of the following types:

- Vertical straight-pipe sparger
- Tee sparger
- Four-armed cross-sparger

Alternative sparger designs are shown in AIChE-CCPS (1998).

The following design criteria are recommended:

1. The flow area of the manifold and/or distributor piping should be at least 2 times the total area of the sparger holes. This generally ensures that flow through the sparger holes will be uniform.
2. The number of holes should provide at least 0.2 hole per square foot (2.2 holes per square meter) of pool cross-sectional area, distributed evenly over the cross section of the pool.
3. Holes should be uniformly spaced in the distributor pipe—adjacent holes should be spaced at least 2 to 3 hole diameters apart, center to center.
4. Holes should discharge from the bottom or bottom half of the distributor pipe so that they can serve also as drains for liquid. Separate drain holes may be needed for the manifold pipe and in each distributor pipe.
5. Holes should be as small as possible consistent with consideration of possible plugging or fouling when handling liquids that contain polymers or suspended solids. For effluent streams consisting of only liquid and vapor, hole diameters ranging from 1/8 to 1/2 in (3 to 13 mm) are typical. Larger hole diameters (up to 2 in) may be required if the blowdown stream contains solids (polymers and/or catalyst). Smaller holes tend to minimize vibration and water hammer.
6. Sonic hole velocity is desirable in smaller holes and is essential in 1/2- to 2-in holes. A minimum sparger pressure drop of 10 psi should be used.
7. The quencher arm should be anchored to prevent pipe whip. It should also extend to the length (for horizontal vessels) or the height (for vertical vessels) of the vessel to evenly distribute the vapors in the pool.

When quenching effluents discharged by safety valves, it is preferable to use a straight, vertical sparger with holes in the end cap as well as in the pipe sidewalls. This is recommended to minimize the possibility of liquid hammer, which can occur more readily in horizontal spargers. The liquid hammer usually occurs for the following reasons: As the relief valve opens for the first time, the pressure spike is cushioned by the air trapped in the vent line. This air is blown out. If the valve recloses, the line may cool, causing slugs of condensate to accumulate. When the valve reopens, the slugs will accelerate to very high velocities and impact any elbows and end caps of the sparger. In severe cases, the sparger-arm end caps can be knocked off. The preceding recommendation avoids turns, and the holes in the end cap provide some relief from the pressure spike.

Many aspects of quench pool design (vessel, spargers, mechanical design loads, etc.) and operation are covered in *Guidelines for Pressure Relief and Effluent Handling Systems* (AIChE-CCPS, 1998), and it should be consulted when a quench pool has to be designed.

**Mass-Transfer Contact Section** Where there is a strong possibility that not all the incoming vapors will be condensed in the pool (the feed stream contains a large amount of noncondensable gases), a direct-contact mass-transfer section is superimposed on the quench tank. This can be a baffle tray section (as shown in Fig. 23-56) or a packed column section.

The design of direct-contact mass-transfer columns is discussed in detail by Scheiman [*Petro Chemical Engr.* 37(3): 29–33, 1965; *ibid.* 37(4): 75, 78–79] and Fair (*Chem. Eng.*, June 12, 1972).

**Emergency Flare Systems** A discussion of design criteria, principles, and practices for a number of flare system components is presented below.

**Flare tip diameter** The flare tip diameter is sized on a velocity basis, but the pressure drop must also be checked. Flare tip velocities can be chosen on the basis of EPA requirements or API recommendations. EPA recommendations are given in the AIChE-CCPS book (1998). API RP 521 states that tips may be based on velocities of 0.5 Mach number or higher, if pressure drop, noise, and other factors permit.

**Flare height and thermal radiation** The height of an elevated flare is based on the minimum distance from the flare flame to an object whose exposure to thermal radiation must be limited. Industrial flares are normally designed so that personnel in the vicinity are not exposed to a heat intensity greater than 1500 to 2000 Btu/(h·ft<sup>2</sup>) when flaring at the maximum design rates.

An equation by Hajek and Ludwig (*Petro/Chem. Eng.* pp. C31–38, June 1960; pp. C44–51, July 1960) may be used to determine the distance required between a flare flame and a point of exposure where thermal radiation must be limited. [See API RP 521 (2007).]

A flame under the influence of wind will tilt in the direction that the wind is blowing and will change the location of the flame center. API RP 521 (2007) presents two methods for estimating the required flare height when the flame is tilted.

Other methods for estimating the required flare height are presented in *Guidelines for Pressure Relief and Effluent Handling Systems* (AIChE-CCPS, 1998).

**Purge gas requirements** Purging is used to prevent the formation of explosive mixtures in flare systems by preventing the admission of air into the system through leaks, backflow of air at the flare tip at very low flows, and back diffusion of air into the flare tip. Combustible gases such as methane or natural gas, or inert gases such as nitrogen or carbon dioxide, are frequently used for purging flare systems. API RP 521 (section 7.3.3.3) presents equations for calculating the purge rate as a function of the stack diameter, the desired oxygen level, and the type of purge gas.

**Air (purge reduction) seals** Air seals (also called purge reduction or gas seals) are often installed near the top of flare stacks. Others are located near the base of the flare. They are used to prevent air from entering the stack and are often recommended to prevent flashbacks and explosions. They also greatly reduce the amount of purge gas required. There are two basic types of air seals primarily used: diffusion (sometimes called molecular or labyrinth seals) and velocity types.

The diffusion seal consists of a baffled concentric cylinder arrangement, which uses the difference in molecular weight of the flare gas and ambient air to prevent air from entering the stack. Diffusion seals, combined with the purge gas flow rate, are intended to form a secondary line of defense against the entry of air into the flare stack. In a vertical flare stack, gravity exerts a driving force to increase the diffusion of air into the stack. Diffusion seals create an inverted flow field to reverse the gravitational effect and reduce air entry. Use of lighter-than-air purge gas (e.g., methane or natural gas)

creates a pocket of light gas at the top of the air entry path. Use of diffusion seal and lighter-than-air purge gas allows a much lower purge gas rate. Installation of a diffusion seal at the top of the flare, and immediately below the burner tip, reduces the purge gas required to 1/50 of the volume required if the diffusion seal is not used (Niemeyer and Livingston, *Chem. Eng. Prog.*, pp. 39–44, December 1993).

Velocity seals are more recent developments in air seal design. They use conical baffles to redirect and focus the purge gas flow field just below the flare tip to sweep air from the flare stack. Some velocity seal designs can reduce the purge gas flow rate requirement to about 1/10 of the rate needed without the seal. Also, some velocity seal designs reportedly require only about 25 to 33 percent of the purge gas used in diffusion seals (AIChE-CCPS, 1998). More details about air (purge reduction) seals may be found in API RP 521 (2007).

**Liquid seal drums** Emergency vent streams are usually passed through a liquid seal, commonly water, before going to the flare stack. The liquid seal drum is usually located downstream of the knockout drum, and some vendors' designs include them in the base of the flare stack. A liquid seal drum is used to maintain a positive pressure in the vent header system and upstream system. It also reduces the possibility of flame flashbacks, caused when air is inadvertently introduced into the flare system and the flame front pulls down into the stack; it also acts as a mechanical damper on any explosive shock wave in the flare stack. Figure 23-58 is a schematic of a typical flare stack liquid seal drum, designed per API RP 521 criteria.

A properly designed and operated liquid seal drum should allow gas to pass through the seal with minimum surging in gas flow and/or upstream gas pressure. The design of the liquid seal internals and the design of the vessel can have a significant impact on the ability of the seal to meet the performance objective. For example, a common design for the end of a dipleg pipe uses V notches cut into the end of the pipe wall. This design is less effective than the proprietary designs developed by vendors of liquid seal drums. These proprietary designs, which use alternative design guidelines, may offer

**FIG. 23-58** Schematic for typical flare stack seal drum. (Adapted from API RP 521.) (Guidelines for Pressure Relief and Effluent Handling Systems, Center for Chemical Process Safety (CCPS) of the American Institute of Chemical Engineers (AIChE); copyright 1988 AIChE and reproduced with permission.).

economic or operational advantages. Details about several types of proprietary designs for liquid seal drums are presented by Grosseil (*Deflagration and Detonation Flame Arresters*, AIChE-CCPS, New York, 2002).

More detailed discussions of flare systems and their components are presented in API RP 521 (2007), API STD 537 (2003), and AIChE-CCPS (1998).

**Emergency Scrubbers (Absorbers)** Emergency relief discharges are often passed through scrubbers (also called absorbers, or absorption columns or towers) for removal of flammable, corrosive, or toxic chemicals. The removal mechanism in some scrubbers involves physical absorption in a solvent, whereas in others chemical absorption (reactive scrubbing) is required.

Unlike quench pools for treatment of emergency relief effluent, scrubbers are not passive. For reliable performance, all critical components, including instruments, must be working correctly. There must be a reliable and sufficient supply of solvent and utilities (cooling water, electricity, etc.), with all process variables maintained under design conditions at all times. This includes proper liquid levels, liquid concentrations, flow rates, and reliable operation of ancillary equipment (e.g., pumps, blowers, etc.). General practice is to provide redundancy in pumps and blowers and utilities to ensure reliable scrubber operation (see Fig. 23-57). In the preferred mode of operation for hazardous materials, especially toxic gases, the scrubber is in a standby mode, with solvent flow maintained at all times. An alternate mode is to have the scrubber shut down (solvent not circulating) and then started up after detecting a release from the pressure relieving system. The consequences of the delay in starting the scrubber up after it has been shut down must be considered before accepting this mode of operation.

A discussion of emergency scrubber design and operating criteria and practices is given in *Guidelines for Pressure Relief and Effluent Handling Systems* (AIChE-CCPS, 1998).

## FLAME ARRESTERS

**General Considerations** In 2002, the Center for Chemical Process Safety (CCPS) of the American Institute of Chemical Engineers (AIChE) published a Concept Book on this topic [8]. The book was intended to expand and update the coverage given in [4], providing extensive information on the history, technology, practice, and regulatory aspects of deflagration and detonation flame arresters.

Flame arresters are passive devices designed to prevent propagation of gas flames through pipelines. Typical applications are to prevent flames entering a system from outside (such as via a tank vent) or propagating within a system (such as from one tank to another). Flame arrestment is achieved by a permeable barrier, usually a metallic matrix containing narrow channels, which removes heat and free radicals from the flame fast enough to both quench it within the matrix and prevent reignition of the hot gas on the protected side of the arrester. These metallic matrices are known as *elements*. Some preliminary considerations for arrester selection and placement are as follows:

1. Identify the at-risk equipment and the potential ignition sources in the piping system to determine where arresters should be placed and what general type (deflagration or detonation, unidirectional or bidirectional) is needed.

2. Determine the worst-case gas mixture combustion characteristics, system pressure, and permissible pressure drop across the arrester, to help select the most appropriate element design. Not only does element design impact pressure drop, but also the rate of blockage due to particle impact, liquid condensation, and chemical reaction (such as monomer polymerization) can make some designs impractical even if in-service and out-of-service arresters are provided in parallel.

3. The possibility of a stationary flame residing on the arrester element surface should be evaluated, and the need for additional safeguards, should such an event occur, should be evaluated (see the subsection Endurance Burn)

4. Consider any material of construction limitations due to reactive or corrosive stream components, plus the impact of elevated temperature and pressure during flame events.

5. Consider upset conditions that could exceed the test conditions at which the arrester was certified. These include the gas composition with regard to concentration of sensitive constituents such as ethylene or hydrogen, maximum system pressure during an emergency shutdown, plus the maximum temperature and oxygen concentration. Under certain upset conditions such as a high-pressure excursion and/or elevated oxygen concentration [14], there may be no flame arrester available for the task.

6. Consider the type and location of the arrester with respect to ease of maintenance, particularly for large in-line arresters.

These questions address the type of arrester needed, the appropriate location, and the best design with respect to flow resistance, maintainability, and cost. It should be recognized that while flame arrester effectiveness is high, it is not 100 percent. To maximize effectiveness, attention should be given to proper selection, application, and maintenance of the device. Since arresters may fail on demand, it is good engineering practice to conduct layers of protection analysis to determine what additional mitigation may be required (Förster, H., *Flame Arresters—The New Standard and Its Consequences*, *Proceedings of the International ESGM Symposium, Part 2: Industrial Explosion Protection*, Nürnberg, Germany, March 27–29, 2001). For marine vapor control systems in the United States, flame arrester applications are regulated by the U.S. Coast Guard. For other applications, alternative test protocols and procedures have been developed by different agencies. Some arresters, such as hydraulic arresters and in-line types used to stop decomposition flames, have specialized applications for which general design and testing information is scarce. Where flame arresters are impractical, alternative strategies such as fast-acting valves, vapor suppression, and flammable mixture control should be considered. Dynamic systems such as fast-acting valves and suppression should be tested and certified as suitable for the required task.

**Combustion: Deflagrations and Detonations** A deflagration is a combustion wave propagating at less than the speed of sound as measured in the unburned gas immediately ahead of the flame front. Flame speed relative to the unburned gas is typically 10 to 100 m/s although owing to expansion of hot gas behind the flame, several hundred meters per second may be achieved relative to the pipe wall. The combustion wave propagates via a process of heat transfer and species diffusion across the flame front, and there is no coupling in time or space with the weak shock front generated ahead of it. Deflagrations typically generate maximum pressures in the range of 8 to 12 times the initial pressure. The pressure peak coincides with the flame front

although a marked pressure rise precedes it; thus the unburned gas is compressed as the deflagration proceeds, depending on the flame speed and vent paths available. The precompression of gas ahead of the flame front (also known as *cascading* or *pressure piling*) establishes the gas conditions in the arrester when the flame enters it, and hence affects both the arrestment process and the maximum pressure generated in the arrester body. A severe deflagration arrestment test involves placing a restricting orifice behind the arrester, which increases the degree of precompression. This is known as *restricted-end* deflagration testing. As discussed later, the *maximum experimental safe gap* (MESG) of the gas mixture may underestimate its tendency to defeat the arrester under such conditions. This is so because the current MESG test method minimizes precompression effects and hence the likelihood of autoignition on the "protected side" of the arrester. It is most important to consider the influences of pressure, temperature, and oxygen concentration on the safe gap. In addition the safe gap of mixtures is influenced by the chemical interaction of the different gases [12, 14].

As the deflagration flame travels through piping, its speed increases due to flow-induced turbulence and compressive heating of the unburned gas ahead of the flame front. Turbulence is especially enhanced by flow obstructions such as valves, elbows, and tees. Once the flame speed has attained the order of 100 m/s, a *deflagration-to-detonation transition* (DDT) can occur, provided that the gas composition is within the detonable limits, which lie inside the flammable limits. The travel distance for this to occur is referred to as the *run-up* distance for detonation. This distance varies with the gas mixture sensitivity and increases with pipe diameter. It is often difficult to estimate the run-up distance at which a DDT may occur in a piping system, and when to specify either a deflagration or a detonation flame arrester. However, some indication of this can be obtained from [13]. If the actual plant piping installation is different from that of the experimental configurations, then it is recommended that tests be conducted simulating the actual plant piping configurations to establish the DDT run-up length. The European Standard EN12 874 [15] limits the use of in-line deflagration arresters to  $L/D = 50$  for group D and C applications and  $L/D = 30$  for group B. Tabulated run-up distances are generally for straight pipe runs, and DDT can occur for much smaller distances in pipe systems containing flow obstructions. At the instant of transition, a transient state of *overdriven detonation* is achieved and persists for a distance of a few pipe diameters. Overdriven detonations propagate at speeds greater than the speed of sound (as measured in the burned gas immediately behind the flame front), and side-on pressure ratios (at the pipe wall) in the range of 50 to 100 have been measured. The peak pressure is variable depending on the amount of precompression during deflagration. A severe test for detonation-type flame arresters is to arrange for the arrester to encounter a series of overdriven detonations.

After the abnormally high velocities and pressures associated with DDT have decayed, a state of stable detonation is attained. A detonation is a combustion-driven shock wave propagating at the speed of sound as measured in the burned gas immediately behind the flame front. Since the speed of sound in this hot gas is much larger than that in the unburned gas or the ambient air, and the flame front speed is augmented by the burned gas velocity, stable detonations propagate at supersonic velocities relative to an external fixed point. A typical velocity for a stoichiometric gas mixture is 1800 m/s. The wave is sustained by chemical energy released by shock compression and ignition of the unreacted gas. The flame front is coupled in space and time with the shock front with no significant pressure rise ahead of the shock front. The high velocities and pressures associated with detonations require special element design to quench the high-velocity flames plus superior arrester construction to withstand the associated impulse loading. Since this entails narrower and/or longer element channels plus bracing of the element facing, both inherent pressure drop and the possibility of fouling of detonation arresters should be considered.

The problem of flame arrestment, of either deflagrations or detonations, depends on the properties of the gas mixture involved plus the initial temperature, pressure, and oxygen concentration. Gas mixture combustion properties cannot be quantified for direct use in

flame arrester selection, and only general characteristics can be assigned. For this reason flame arrester performance must be demonstrated by realistic testing. Such testing has demonstrated that arresters capable of stopping even overdriven detonations may fail under restricted end deflagration test conditions. It is important to understand the significance of the test conditions addressed and their possible limitations. It is recommended that users request a detailed test report from the flame arrester manufacturer and only an approved arrester tested to a recognized test standard be installed.

**Combustion: Gas Characteristics and Sensitivity** Combustion thermodynamic calculations allow determination of peak deflagration and detonation pressures, plus stable detonation velocity. The peak pressure calculation may be used to determine combustion product venting requirements although a conservative volume increase of 9:1 may be used for essentially closed systems. Other relevant gas characteristics are entirely experimental. The sensitivity to detonation depends on the detonable range and fundamental burning velocity, although no specific correlations or measures of sensitivity exist based on fundamental properties. National Electrical Code (NEC) groups are commonly used to rank gases for the purposes of flame arrester selection. By this method, group A gases (acetylene) are considered most sensitive to detonation (and most difficult to arrest) while group D gases (such as saturated hydrocarbons) are considered least sensitive and easiest to arrest. As formerly applied, successful testing of an arrester using one gas in a NEC Electrical Group was assumed to mean that the arrester would be suitable for all other gases in that group. As presently applied in various codes, a representative test gas from each group (such as hydrogen in group B, ethylene in group C, or propane in group D) is typically used for arrester certification, and its ability to arrest a different gas or gas mixture is deduced by comparing the respective maximum experimental safe gaps. The arrester is assumed to be suitable for any single gas or mixture having an MESG greater than or equal to that of the representative test gas. Although the arrester may be directly tested using the gas or gas mixture of interest, this is rarely carried out owing to cost. The MESG comparison procedure is currently applied to both deflagration and detonation arresters. Specific testing protocols are specified by the codes used. Since MESGs provide an independent ranking for arrester selection, reference to NEC groups is not essential. Nevertheless, arresters continue to be described in terms of the NEC group of the representative test gas used for certification. For example, an arrester might be described as a "group C (ethylene)" type. A detailed discussion of the use of MESGs is given in [9].

It is cautioned that there have been no systematic studies proving that arrester performance can be directly correlated with MESG, especially if the MESG for a mixture is estimated by using the Le Chatelier rule. An alternative way for calculating the MESG and safe gap of mixtures is given in [12]. Furthermore, major revisions to the MESG test method have caused many "historic" MESG values to increase significantly; the current test method minimizes compression of the unburned gas mixture and may therefore underestimate the likelihood of arrester failure via autoignition.

**Corrosion** Consideration should be given to possible corrosion of both the element material and the arrester housing, since corrosion may weaken the structure, increase the pressure drop, and decrease the effectiveness of the element. While the housing might be designed to have a corrosion allowance, corrosion of the element must be avoided by proper material specification. Common materials of construction include aluminum, carbon steel, ductile iron and 316 stainless steel housings, and aluminum or 316 stainless steel elements. While special materials such as Hastelloy might be used for situations such as high HCl concentrations, it may be more cost-effective to use a hydraulic arrester made of carbon steel and lined with a suitable polymeric lining in such applications. Also, at least one flame arrester manufacturer can provide flame arresters with PTFE (Teflon) arresting elements and lined housings up to a nominal size of 4 in for very corrosive service [8].

**Directionality** To select an arrester for any service, the potential sources of ignition must be established in relation to the pipe system and the equipment to be protected. The pipe connecting an arrester with an identified ignition source is the *unprotected side* of the arrester.

The pipe connecting the arrester with at-risk equipment is the *protected side*. If the arrester will encounter a flame arriving only from one direction, a *unidirectional* arrester can be used. If a flame may arrive from either direction a *bidirectional* arrester is needed. The latter either are symmetrically constructed or are certified by testing. Back-to-back use of unidirectional arresters will not usually be cost-effective unless testing reveals a specific advantage such as increased allowable operating pressure during restricted end deflagration testing.

**Endurance Burn** Under certain conditions a successfully arrested flame may stabilize on the unprotected side of an arrester element. Should this condition not be corrected, the flame will eventually penetrate the arrester as the channels become hot. An endurance burn time can be determined by testing, which specifies that the arrester has withstood a stabilized flame without penetration for a given period. The test should address either the actual or the worst-case geometry since heat transfer to the element will depend on whether the flame stabilizes on the top, bottom, or horizontal face. In general the endurance burn time identified by test should not be regarded as an accurate measure of the time available to take remedial action, since test conditions will not necessarily approximate the worst possible practical case. Temperature sensors may be incorporated at the arrester to indicate a stabilized flame condition and either alarm or initiate appropriate action, such as valve closure. It is very important to install an endurance burning flame arrester in the same way as tested to avoid malfunction [11].

**Installation** End-of-line arresters should be protected by using appropriate weather hoods or cowls. In-line arresters (notably detonation arresters and in-line deflagration arresters) must be designed to withstand the highest line pressure that might be seen, including upset conditions. The design should be verified by hydrostatic and pneumatic pressure tests. The piping system should be designed with adequate supports and should allow routine access to the arrester for inspection and maintenance.

**Maintenance** It is important to provide for arrester maintenance by both selection of the most suitable arrester type and judicious location. Inspection and maintenance should be performed on a regular basis depending on experience with the particular arrester in the service involved. It should also be carried out after successful function of the arrester. Some in-line designs allow removal, inspection, and cleaning of the element without the need to expand the line. Unit designs featuring multiple elements in parallel can reduce downtime by extending the period between cleaning. For systems that cannot be shut down during maintenance, parallel arresters incorporating a three-way valve may be used. Detonation arrester elements are especially prone to damage during dismantling, cleaning, and reassembly. Maintenance must be carefully done, avoiding sharp objects that could disable the delicate channels in the element. Spare elements should be available to reduce downtime and provisions made for storing, transporting, and cleaning the elements without damage.

**Monitoring** The differential pressure across the arrester element can be monitored to determine the possible need for cleaning. The pressure taps must not create a flame path around the arrester. It can be important to provide temperature sensors such as thermocouples at the arrester to detect flame arrival and stabilization. Since arrester function may involve damage to the arrester, the event of successful function (flame arrival) may be used to initiate inspection of the element for damage. If the piping is such that flame stabilization on the element is a realistic concern, action must be taken immediately upon indication of such stabilization (see also Endurance Burn). Such action may involve valve closure to shut off gas flow or inert gas purging.

**Operating Temperature and Pressure** Arresters are certified subject to maximum operating temperatures and absolute pressures normally seen at the arrester location. Arrester placement in relation to heat sources such as incinerators must be selected so that the allowable temperature is not exceeded, with due consideration for the detonation potential as run-up distance is increased. Flame arrester manufacturers can provide recommended distances from heat sources, such as open flames, to avoid thermal damage to a flame arrester element. If heat tracing is used to prevent condensation of liquids, the same temperature constraint applies. In the case of in-line arresters, there may

be certain upset conditions that produce unusually large system pressures outside the stipulated operating range of the arrester. Since the maximum operating pressure for a detonation arrester may be in the range of 16 to 26 psia, depending on the gas sensitivity and arrester design, it may be impossible to find a suitable arrester to operate during such an upset. The situation may be exacerbated by pressure drop across the device caused by high flow and/or fouling.

**Pressure Drop** Flow resistance depends on flame arrester channel arrangement and on a time-dependent fouling factor due to corrosion, or accumulation of liquids, particles or polymers, depending on the system involved. Monomer condensation is a difficult problem since inhibitors will usually be removed during monomer evaporation and catalysis might occur over particulates trapped in the element. Pressure drop can be a critical factor in operability, and cleaning may represent a large hidden cost. Sizing for pressure drop must be based on worst-credible-case operating conditions rather than normal operating conditions.

Fouling may be mitigated in a number of ways. First, the least sensitive element design can be selected, and in the case of end-of-line arresters, weather hoods or cowls can be used to protect against water or ice accumulation. Second, a fouling factor (20 percent or greater) might be estimated and an element with a greater tested flow capacity selected to reduce the pressure drop. This should be further increased if liquid condensation might occur. It is important that certified flow curves for the arrester be used rather than calculated curves since the latter can be highly optimistic. Condensation and polymerization may be mitigated by geometry (minimizing liquid accumulation in contact with the element) and provision for drainage. Alternatively, the arrester may be insulated and possibly heat-traced. Drains should not provide flame paths around the arrester or leak in either direction when closed. If heat tracing is used, the temperature must be limited to the certified operating range of the arrester.

In addition to using an arrester element with greater flow capacity, it is common to use two arresters in parallel where frequent cleaning is required, with one arrester in standby. A three-way valve can be used to allow uninterrupted operation during changeover. Where elements have an intrinsically high pressure drop, such as sintered metal elements used in acetylene service, multiple parallel elements can be used.

**Deflagration Arresters** The two types of deflagration arrester normally encountered are the *end-of-line arrester* (Figs. 23-59 and 23-60) and the *tank vent deflagration arrester*, which is mounted close to the end of the line going direct to the atmosphere. Neither type of arrester is designed to stop in-line deflagrations or detonations. If mounted sufficiently far from the atmospheric outlet of a piping system, which constitutes the unprotected side of the arrester, the flame can accelerate sufficiently to cause these arresters to fail. Failure can occur at high flame speeds even without a run-up to detonation.

If atmospheric tanks are equipped with flame arresters on the vents, fouling or blockage by extraneous material can inhibit gas flow to the degree that the tank can be damaged by underpressure. API standards allow the use of pressure vacuum (P/V) valves without flame arresters for free-venting tanks on the basis that the high vapor velocity in the narrow gap between pressure pallet (platter) and valve body will prevent flashback. However, it is important to ensure the pallet is not missing or stuck open since this will remove the protection. Absence of the pallet was a listed factor in the 1991 Coode Island fire (State Coroner Victoria, Case No. 2755/91, Inquest into Fire at Coode Island on August 21 and 22, 1991, Finding). Whether or not flame arresters are used, proper inspection and maintenance of these vent systems is required.

**End-of-line arresters** are mounted at the outlet of a pipe system and go directly to the atmosphere, so there is no potential for significant flame acceleration in the pipe. **Tank vent deflagration arresters** are strictly limited by the approval agency, but for group D gases they are typically mounted no more than 20 ft from the end of a straight pipe that vents directly to the atmosphere. The allowed distance must be established by proper testing with the appropriate gas mixture and the pipe diameter involved. Turbulence-promoting irregularities in the flow (bends, tees, elbows, valves, etc.) cannot be used unless testing has addressed the exact geometry. It is essential that run-up to detonation not occur in the

FIG. 23-59 Typical end-of-line deflagration arrester installations. (Courtesy of PROTEGO®.)

available piping system, and run-up distance can be less than 2 ft for some fast-burning gases such as hydrogen in air (group B). Thus the NEC grouping of the gas mixture must be considered. More importantly, it must be emphasized that even if run-up to detonation does not occur, a deflagration arrester can fail if the flame speed is great enough. Thus the run-up distance is not an adequate criterion for acceptable location, and this limitation can be determined only by realistic testing. A number of explosions have occurred due to misapplication of end-of-line or tank vent deflagration arresters where detonation arresters or in-line deflagration arresters should have been used. The latter are described in the next subsection.

**Detonation and Other In-Line Arresters** If the point of ignition is remote from the arrester location, the arrester is an in-line type such as might be situated in a vapor collection system connecting several tanks. Due to the possibility of DDT, most in-line arresters are designed to stop both deflagrations and detonations (including overdriven detonations) of the specified gas mixture. These are known as **detonation arresters**. Figure 23-61 shows a typical design. Detonation arresters may be further delineated into those types that will arrest only stable detonations and those that will arrest both stable and unstable detonations (i.e., overdriven detonations or DDT events).

In some cases, in-line arresters need to stop deflagrations only. However, in such cases it must be demonstrated that detonations

cannot occur in the actual pipework system; unless the gas mixture is intrinsically not capable of detonation, this requires full-scale testing using the exact pipe geometry to be used in practice, which must not be changed after installation. In certain exceptional cases, an in-line deflagration arrester may be mounted without regard to run-up distance. This can be done only where the system is known to be incapable of detonation. Examples are the decomposition flames of ethylene and ethylene oxide, which are briefly discussed under Special Arrester Types and Alternatives.

Detonation arresters are typically used in conjunction with other measures to decrease the risk of flame propagation. For example, in vapor control systems the vapor is often enriched, diluted, or inerted, with appropriate instrumentation and control [5]. In cases where ignition sources are present or predictable (such as most vapor destruct systems), the detonation arrester is used as a last-resort method anticipating possible failure of vapor composition control. Where vent collection systems have several vapor/oxidant sources, stream compositions can be highly variable and this can be additionally complicated when upset conditions are considered. It is often cost-effective to perform hazard analyses such as HAZOP or fault

FIG. 23-60 Typical end-of-line deflagration arrester design. (Courtesy of PROTEGO®.)

FIG. 23-61 Typical detonation arrester design (crimped ribbon type). (Courtesy of PROTEGO®.)

tree analysis to determine whether such vent streams can enter the flammable region and, if so, what composition corresponds to the worst credible case. Such an analysis is also suitable to assess alternatives to arresters.

**Effect of Pipe Diameter Changes** Arrester performance can be impaired by local changes in pipe diameter. It was shown that a minimum distance of 120 pipe diameters should be allowed between the arrester and any increase in pipe diameter; otherwise, a marked reduction in maximum allowable operating pressure would occur. This impairment was observed during detonation testing but was most pronounced during restricted-end deflagration testing (Lapp and Vickers, *Int. Data Exchange Symp. on Flame Arresters and Arrestment Technology*, Banff, Alberta, October 1992). As a rule, arresters should be mounted in piping either equal to or smaller than the nominal size of the arrester.

**Venting of Combustion Products** As gas deflagrates or detonates in the piping system, there is a volume expansion of the products and an associated pressure increase. In some instances where the pipe system volume involved is relatively large, a significant overpressure might be developed in the vapor spaces of connected tanks, especially when vapor space is minimal due to high liquid level. It can be assumed that all the gas on the unprotected side of the arrester is converted to equilibrium products; the pressure is relieved via gas expansion into the entire system volume and to the atmosphere via any vent paths present. If heat losses are neglected by the assumption of high flame speeds or detonation, and atmospheric venting paths are neglected, a conservative approach is that storage vessels be designed with a capacity to handle 9 times the pipe volume on the unprotected side of the arrester. With regard to the high pressures associated with detonations, it has been shown (Lapp, Independent Liquid Terminal Association Conference, Houston, June 23, 1992) that detonation arresters attenuate the peak detonation pressure by up to 96 percent depending on the arrester design, and therefore protect from much of the pressure pulse. To further reduce the pressure pulse, relief devices may be provided at the arrester.

**Arrester Testing and Standards** Regulatory and approval agencies and insurers impose *acceptance testing* requirements, sometimes as part of certification standards. The user may also request testing to demonstrate specific performance needs just as the manufacturer can help develop standards. These interrelationships have resulted in several new and updated performance test procedures. Listing of an arrester by a testing laboratory refers only to performance under a defined set of test conditions. The flame arrester user should develop specific application requirements based on the service involved and the safety and risk criteria adopted.

As discussed in [8], a variety of test procedures and use guidelines have been developed. General considerations are given in Chapter 9.3 of National Fire Protection Association Standard 69. The Federal Register, 33 CFR, Part 154, contains the USCG requirements for detonation arresters in marine vapor control systems. Other U.S. procedures are given in ASTM F 1273-91, UL 525, FM Procedure Classes 6061 and 7371, plus API Publications 2028 and 2210. For U.S. mining applications, the Mine Safety and Health Administration (MSHA) provides regulation and guidance; e.g., in CFR Title 30, Part 36. The International Maritime Organization (IMO) Standard MSC/Circ. 677 (1994) provides testing procedures for end-of-line deflagration and in-line detonation arresters for use on tanker ships. In Canada, CSA-Z343 is followed while in Europe the CEN Standard EN 12874 [15] has replaced previous European National Standards such as BS 7244.

**Deflagration Arrester Testing** For end-of-line, tank vent, and in-line deflagration flame arresters, approval agencies may require manufacturers to provide users with data for flow capacity at operating pressures, proof of success during an endurance burn or continuous flame test, evidence of flashback test results (for end-of-line arresters) or explosion test results (for in-line or tank vent arrester applications), hydraulic pressure test results, and results of a corrosion test.

Endurance burn testing generally implies that the ignited gas mixture and flow rate are adjusted to give the worst-case heating (based on temperature observations on the protected side of the element surface), that the burn continues for a specified duration, and flame penetration does not occur. Continuous flame testing implies a gas

mixture and flow rate are established at specified conditions and burn on the flame arrester for a specified duration. The endurance burn test is usually a more severe test than the continuous burn. In both cases the flame arrester attachment configuration and any connecting piping or valves should be installed in the same configuration used for testing. General reference [11] gives additional information.

Flashback tests incorporate a flame arrester on top of a tank with a large plastic bag surrounding the flame arrester. A specific gas mixture (e.g., propane, ethylene, or hydrogen at the most sensitive composition in air) flows through and fills the tank and the bag. Deflagration flames initiated in the bag (three at different bag locations) must not pass through the flame arrester into the protected vessel. On the unprotected side, piping and attachments such as valves are included as intended for installation; a series of tests, perhaps 10, is conducted.

Whatever the application, a user should be aware that not all test procedures are the same, or of the same severity, or use the same rating designations. Therefore, it is important to review the test procedure and determine whether the procedure used is applicable to the intended installation and potential hazard the flame arrester is meant to prevent.

**Detonation Arrester Testing** Requirements are described by various agencies in the documents listed above (UL 525, etc). For installations governed by the USCG in Appendix A of 33 CFR, Part 154 (Marine Vapor Control Systems), the USCG test procedures must be followed. These are similar but not identical to those of other agencies listed. The European Union mandates arrester testing by an approved testing laboratory according to the EN 12874 Standard. Reference [8] discusses differences between the requirements of disparate agencies.

Detonation arresters are extensively tested for proof of performance against deflagrations, detonations, and endurance burns. In the United States, arrester manufacturers frequently test detonation arresters according to the USCG protocol; other test standards might alternatively or additionally be met. Under this protocol, the test gas must be selected to have either the same or a lower MESH than the gas in question. Typical MESH benchmark gases are stoichiometric mixtures of propane, hexane, or gasoline in air to represent group D gases having an MESH equal to or greater than 0.9 mm, and ethylene in air to represent group C gases with an MESH no less than 0.65 mm. Commercially available arresters are typically certified for use with one or another of these benchmark gas types. An ethylene-type arrester is selected, should the gas in question have an MESH of less than 0.9 mm but not less than 0.65 mm. Five low and five high overpressure deflagration tests are required with and without a flow restriction on the protected side. Of these 20 tests, the restricted-end condition is usually the most severe and often limits the maximum initial pressure at which the arrester will be suitable. Five detonation tests and five overdriven detonation tests are also required, which may involve additional run-up piping and turbulence promoters to achieve DDT at the arrester. If these tests are successful, an endurance burn test is required. This test does not use propane for group D gases but hexane or gasoline, owing to their lower autoignition temperatures. For group C tests, ethylene can be used for all test stages.

Care must be taken when applying the MESH method [4, 9, 12]. The user has the option to request additional tests to address such concerns and may wish to test actual stream compositions rather than simulate them on the basis of MESH values.

### Special Arrester Types and Alternatives

**Hydraulic (Liquid Seal) Flame Arresters** Hydraulic (liquid seal) flame arresters are most commonly used in large-pipe-diameter systems where fixed-element flame arresters are either cost-prohibitive or otherwise impractical (e.g., very corrosive gas or where the gas contains solid particles that would quickly plug a conventional arrester element). These arresters contain a liquid, usually water-based, to provide a flame barrier. Figure 23-62 shows one design. Realistic tests are needed to ensure performance, as described in EN 12874 [15]. Note that hydraulic flame arresters may fail at high flow rates, producing a sufficiently high concentration of gas bubbles to allow transmission of flame. This is distinct from the more obvious failure mode caused by failure to maintain adequate liquid level.

**Alternatives to Arresters** Alternatives to the use of flame arresters include fast-acting isolation valves, vapor suppression systems,

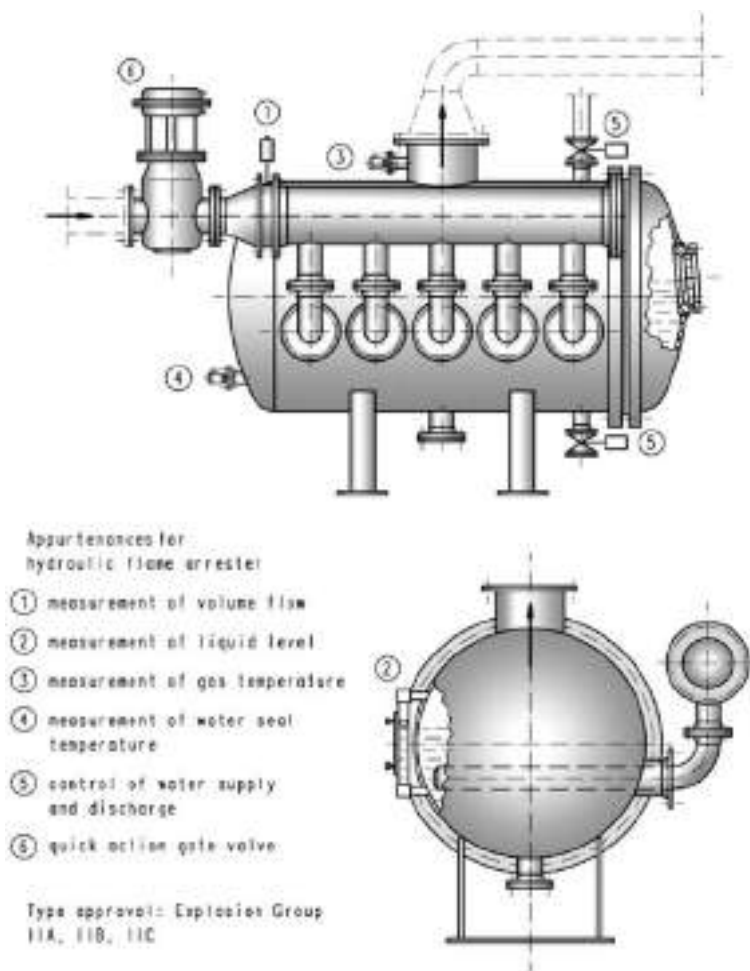

FIG. 23-62 Tested and approved hydraulic (liquid seal) flame arrester. (Courtesy of PROTEGO®.)

velocity-type devices in which gas velocity is designed to exceed flashback velocity, and control of the flammable mixture (NFPA 69 Standard, "Explosion Prevention Systems"). The latter alternative frequently involves reduction of oxygen concentration to less than the limiting oxygen concentration (LOC) of the gas stream.

**Introduction** The inherent nature of most chemicals handled in the chemical process industries is that they each have physical, chemical, and toxicological hazards to a greater or lesser degree. This requires that these hazards be contained and controlled throughout the entire life cycle of the facility, to avoid loss, injury, and environmental damage. The provisions that will be necessary to contain and control the hazards will vary significantly depending on the chemicals and process conditions required.

**Established Practices** Codes, standards, regulatory requirements, industry guidelines, recommended practices, and supplier specifications have all developed over the years to embody the collective experience of industry and its stakeholders in the safe handling of specific materials. These should be the engineer's first resource in seeking to design a new facility.

The ASME Boiler and Pressure Vessel Code, Section VIII, is the standard resource for the design, fabrication, installation, and testing of storage tanks and process vessels rated as pressure vessels (i.e., above 15-psig design). ASME B31.3 is a basic resource for process piping systems.

Examples of established practices and other resources—some of which pertain to the safe storage and handling of specific hazardous chemicals, classes of chemicals, or facilities—include those listed in Table 23-29 from the publications of two U.S. organizations, the NFPA and the Compressed Gas Association (CGA). Other organizations that may have pertinent standards include the International Standards Organization (ISO), the American National Standards Institute (ANSI), ASTM International (Conshohocken, Pa; [www.astm.org](http://www.astm.org)), and other well-established national standards such as British Standards and Deutsches Institut für Normung e.V. (DIN) standards. Local codes and regulations should be checked for applicability, and the latest version should always be used when employing established practices.

**Basic Design Strategies** The storage and handling of hazardous materials involve risks that can be reduced to very low levels by good planning, design, and management practices. Facilities that handle hazardous materials typically represent a variety of risks, ranging from small leaks, which require prompt attention, to large releases, which are extremely rare in well-managed facilities but which have the potential for widespread impact (CCPS, 1988). It is essential that good techniques be developed for identifying significant hazards and mitigating them where necessary. Hazards can be identified and evaluated by using approaches discussed in the section on hazard and risk analysis.

Loss of containment due to mechanical failure or improper operation is a major cause of chemical process incidents. The design of storage and piping systems should be based on minimizing the likelihood of loss of containment, with the accompanying release of hazardous materials, and on limiting the amount of the release. An effective emergency response program that can reduce the impacts of a release should be available.

Thus, the basic design strategy for storing and handling hazardous materials can be summarized as follows, with reference to other parts of this section in parentheses:

1. Understand the hazardous properties of the materials to be stored and handled (Flammability, Reactivity, Toxicity, Other Hazards), as well as the physical hazards associated with the expected process design.

2. Reduce or eliminate the underlying hazards as much as is feasible (Inherently Safer and More User-Friendly Design).

3. Evaluate the potential consequences associated with major and minor loss-of-containment events and other possible emergency situations involving the hazardous materials and energies; and take this information into account in the process of site selection and facility layout and the evaluation of the adequacy of personnel, public, and environmental protection (Source Models, Atmospheric Dispersion, Estimation of Damage Effects).

4. Design and build a robust and well-protected primary containment system following codes, standards, regulations, and other established practices (Security).

NOTE: Always check the latest edition when using established practices.

5. Design and implement a reliable and fault-tolerant basic process control system to ensure the design limitations of the primary containment system are not exceeded.

6. Include provisions for detecting abnormal process conditions and bringing the process to a safe state before an emergency situation occurs (Safety Instrumented Systems).

7. Design, install, and maintain reliable and effective emergency relief systems, as well as mitigation systems such as secondary containment, deluge, and suppression systems, to reduce the severity of consequences in the event an emergency situation does occur (Pressure Relief Systems; Emergency Relief Device Effluent Collection and Handling).

8. Evaluate the risks associated with the process and its safety systems taken as a whole, including consideration of people, property, business, and the environment, that could be affected by loss events; and determine whether the risks have been adequately reduced (Hazard Analysis, Risk Analysis, Source Models, Atmospheric Dispersion, Estimation of Damage Effects).

9. Take human factors into account in the design and implementation of the control system and the facility procedures (Human Error, Key Procedures).

10. Ensure staffing, training, inspections, tests, maintenance, and management of change are all adequate to maintain the integrity of the system throughout the facility lifetime (Key Procedures, Audit Process).

Designers and operating companies will address these items in different ways, according to their established procedures. The steps that are addressed elsewhere in this section are not repeated here.

**Site Selection, Layout, and Spacing** Facility siting decisions that will have critical, far-reaching implications are made very early in a new facility's life cycle, or in the early planning stages of a site expansion project. The degree of public and regulatory involvement in this decision-making process, as well as the extent of prescriptive requirements and established practices in this area, varies considerably among countries, regions, and companies. Insurance carriers are also generally involved in the process, particularly with regard to fire protection considerations.

From the perspective of process safety, key considerations with respect to site selection, layout, and spacing can be summarized as

- Where on-site personnel (including contractors and visitors), critical equipment, the surrounding public, and sensitive environmental receptors are located with respect to hazardous materials and processes
- Whether the design and construction of control rooms and other occupied structures, as well as detection, warning, and emergency response provisions, will provide adequate protection in the event of a major fire, explosion, or toxic release event

Recommended distances for spacing of buildings and equipment for fire protection were issued as IRI IM.2.5.2, *Plant Layout and Spacing for Oil and Chemical Plants* (Industrial Risk Insurers, Hartford, Conn). These are referenced in "Typical Spacing Tables" included as Appendix A of the CCPS *Guidelines for Facility Siting and Layout* (2003). Other resources pertaining to siting and layout include

- *Dow's Fire & Explosion Index Hazard Classification Guide*, 7th ed. (AIChE, New York, 1994), which gives an empirical radius of exposure and damage factor based on the quantity and characteristics of the material being stored and handled
- API RP 752, "Management of Hazards Associated With Location of Process Plant Buildings," 2d ed. (American Petroleum Institute, Washington, 2003), which gives a risk-based approach to evaluating protection afforded by occupied structures

## Storage

**Storage Facilities** Dating back to at least 1974, when a vapor cloud explosion in Flixborough, U.K., claimed 28 lives and destroyed an entire chemical plant (Mannan, 2005), a major emphasis in the safe storage and handling of hazardous materials has been to reduce hazardous material inventories. Inventory reduction can be accomplished not only by using fewer and smaller storage tanks and vessels but also by eliminating any nonessential intermediate storage vessels and

batch process weigh tanks and generating hazardous materials on demand when feasible. Note, however, that reduction of inventory may require more frequent and smaller shipments and improved management.

There may be more chances for errors in connecting and reconnecting with small shipments. Quantitative risk analysis of storage facilities has revealed solutions that may run counter to intuition. [Schaller, *Plant/Oper. Prog.* 9(1), 1990]. For example, reducing inventories in tanks of hazardous materials does little to reduce risk in situations where most of the exposure arises from the number and extent of valves, nozzles, and lines connecting the tank. Removing tanks from service altogether, on the other hand, generally helps. A large pressure vessel may offer greater safety than several small pressure vessels of the same aggregate capacity because there are fewer associated nozzles and lines. Also, a large pressure vessel is inherently more robust, or it can economically be made more robust by deliberate overdesign than can a number of small vessels of the same design pressure. On the other hand, if the larger vessel has larger connecting lines, the relative risk may be greater if release rates through the larger lines increase the risk more than the inherently greater strength of the vessel reduces it. In transporting hazardous materials, maintaining tank car integrity in a derailment is often the most important line of defense in transportation of hazardous materials.

**Safer Storage Conditions** The hazards associated with storage facilities can often be reduced significantly by changing storage conditions. The primary objective is to reduce the driving force available to transport the hazardous material into the atmosphere in case of a leak (Hendershot, 1988). Some methods to accomplish this follow.

**Dilution** Dilution of a low-boiling hazardous material reduces the hazard in two ways:

1. The vapor pressure is reduced. This has a significant effect on the rate of release of material boiling at less than ambient temperature. It may be possible to store an aqueous solution at atmospheric pressure, such as aqueous ammonium hydroxide instead of anhydrous ammonia.
2. In the event of a spill, the atmospheric concentration of the hazardous material will be reduced, resulting in a smaller hazard downwind of the spill.

**Refrigeration** Loss of containment of a liquefied gas under pressure and at atmospheric temperature causes immediate flashing of a large proportion of the gas. This is followed by slower evaporation of the residue. The hazard from a gas under pressure is normally much less in terms of the amount of material stored, but the physical energy released if a confined explosion occurs at high pressure is large.

Refrigerated storage of hazardous materials that are stored at or below their atmospheric boiling points mitigates the consequences of containment loss in three ways:

1. The rate of release, in the event of loss of containment, will be reduced because of the lower vapor pressure in the event of a leak.
2. Material stored at a reduced temperature has little or no superheat, and there will be little flash in case of a leak. Vaporization will be mainly determined by liquid evaporation from the surface of the spilled liquid, which depends on weather conditions.
3. The amount of material released to the atmosphere will be further reduced because liquid entrainment from the two-phase flashing jet resulting from a leak will be reduced or eliminated.

Refrigerated storage is most effective in mitigating storage facility risk if the material is refrigerated when received.

The economics of storage of liquefied gases are such that it is usually attractive to use pressure storage for small quantities, pressure or semirefrigerated storage for medium to large quantities, and fully refrigerated storage for very large quantities. Quantitative guidelines can be found in Mannan (2005).

It is generally considered that there is a greater hazard in storing large quantities of liquefied gas under pressure than at low temperatures and low pressures. The trend is toward replacing pressure storage by refrigerated low-pressure storage for large inventories. However, it is necessary to consider the risk of the entire system, including the refrigeration system, and not just the storage vessel. The consequences of failure of the refrigeration system must be considered. Each case should be carefully evaluated on its own merits.

**Preventing Leaks and Spills from Accumulating under Tanks or Equipment** Around storage and process equipment, it is a good idea to design dikes that will not allow toxic and flammable materials to accumulate around the bottom of tanks or equipment in case of a spill. If liquid is spilled and ignites inside a dike where there are storage tanks or process equipment, the fire may be continuously supplied with fuel and the consequences can be severe. It is usually much better to direct possible spills and leaks to an area away from the tank or equipment and provide a firewall to shield the equipment from most of the flames if a fire occurs. Figure 23-63 shows a diking design for directing leaks and spills to an area away from tanks and equipment.

The surface area of a spill should be minimized for hazardous materials that have a significant vapor pressure at ambient conditions, such as acrylonitrile or chlorine. This will make it easier and more practical to collect vapor from a spill or to suppress vapor release with foam or by other means. This may require a deeper nondrained dike area than normal or some other design that will minimize surface area, in order to contain the required volume. It is usually not desirable to cover a diked area to restrict loss of vapor if the spill consists of a flammable or combustible material.

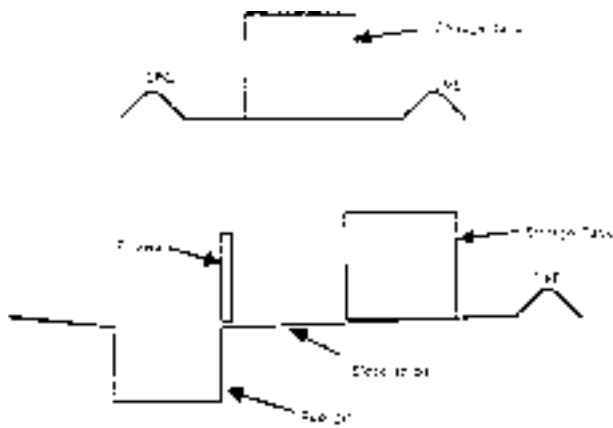

**Minimal Use of Underground Tanks** The U.S. Environmental Protection Agency's (EPA) Office of Underground Storage Tanks defines underground tanks as those with 10 percent or more of their volume, including piping, underground. An aboveground tank that does not have more than 10 percent of its volume (including piping) underground is excluded from the underground tank regulations. Note, however, that a 5000-gal tank sitting wholly atop the ground but having 1400 ft of 3-in buried pipe or 350 ft of 6-in buried pipe is considered an underground storage tank.

At one time, burying tanks was recommended because it minimized the need for a fire protection system, dikes, and distance separation. At many companies, this is no longer considered good practice. Mounding, or burying tanks above grade, has most of the same problems as burying tanks below ground and is usually not recommended.

Problems with buried tanks include

- Difficulty in monitoring interior and exterior corrosion (shell thickness)
- Difficulty in detecting leaks
- Difficulty of repairing a tank if the surrounding earth is saturated with chemicals from a leak
- Potential contamination of groundwater due to leakage

Government regulations concerning buried tanks have become stricter. This is so because of the large number of leaking tanks that

**FIG. 23-63** Methods of diking for flammable liquids: (a) traditional diking method allows leaks to accumulate around the tank. In case of fire, the tank will be exposed to flames that can be supplied by fuel from the tank and will be hard to control. (b) In the more desirable method, leaks are directed away from the tank. In case of fire, the tank will be shielded from most flames and fire will be easier to fight. (From Englund, in *Advances in Chemical Engineering*, vol. 15, Academic Press, San Diego, 1990, pp. 73-135, by permission.)

have been identified as causing adverse environmental and human health problems.

**Design of Tanks, Piping, and Pumps** Six basic tank designs are used for the storage of organic liquids: (1) fixed-roof, (2) external floating-roof, (3) internal floating-roof, (4) variable vapor space, (5) low-pressure, and (6) high-pressure tanks. The first four tank designs listed are not generally considered suitable for highly toxic hazardous materials.

**Low-Pressure Tanks (up to 15 psig)** Low-pressure storage tanks for highly hazardous toxic materials should meet, as a minimum, the American Petroleum Institute (API) 620 Standard, "Recommended Rules for the Design and Construction of Large Welded, Low-Pressure Storage Tanks" (*API Standards*). This standard covers above-ground tanks designed for all pressures less than or equal to 15 psig and metal temperatures less than or equal to 250°F (121°C). There are no specific requirements in API 620 for highly hazardous toxic materials.

API 650, "Welded Steel Tanks for Oil Storage" (*API Standards*), has limited applicability to storage of highly hazardous toxic materials because it prohibits refrigerated service and limits pressures to 2.5 psig and only if designed for certain conditions. Most API 650 tanks have a working pressure approaching atmospheric pressure, and hence their pressure-relieving devices must generally vent directly to the atmosphere. Its safety factors and welding controls are less stringent than required by API 620.

Horizontal and vertical cylindrical tanks are used to store highly toxic liquids and other hazardous materials at atmospheric pressure. Horizontal, vertical, and spherical tanks are used for refrigerated liquefied gases that are stored at atmospheric pressure. The design pressure of tanks for atmospheric pressure and low-pressure storage at ambient temperature should not be less than 100 percent of the vapor pressure of the material at the maximum design temperature. The maximum design metal temperature to be used takes into consideration the maximum temperature of material entering the tank; the maximum ambient temperature, including solar radiation effects; and the maximum temperature attainable by expected or reasonably foreseeable abnormal chemical reactions.

Since discharges of vapors from highly hazardous materials cannot simply be released to the atmosphere, the use of a weak seam roof is not normally acceptable. It is best that tanks in low-pressure hazardous service be designed and stamped for 15 psig to provide maximum safety, and pressure relief systems must be provided to vent relieved overpressure to equipment that can collect, contain, and treat the effluent.

The minimum design temperature should be the lowest temperature to which the tank will be subjected, taking into consideration the minimum temperature of material entering the tank, the minimum temperature to which the material may be autorefrigerated by rapid evaporation of low-boiling liquids or mechanically refrigerated, the minimum ambient temperature of the area where the tank is located, and any possible temperature reduction by endothermic physical processes or chemical reactions involving the stored material. API 620 provides for installations in areas where the lowest recorded 1-day mean temperature is 50°F (10°C).

While either rupture disks or relief valves are allowed on storage tanks by Code, rupture disks by themselves should not be used on tanks for the storage of toxic or other highly hazardous materials since they do not close after opening and may lead to continuing release of hazardous material to the atmosphere.

The API 620 Code requires a combined pneumatic hydrotest at 125 percent of design tank loading. In tanks designed for low-density liquid, the upper portion is not fully tested. For highly hazardous materials, consideration should be given for hydrotesting at the maximum specified design liquid level. It may be required that the lower shell thickness be increased to withstand a full head of water and that the foundation be designed such that it can support a tank full of water or the density of the liquid, if it is greater than water. Testing in this manner not only tests the containment capability of the tank, but also provides an overload test for the tank and the foundation similar to the overload test for pressure vessels. API 620 also requires radiography.

Proper preparation of the subgrade and grade is extremely important for tanks that are to rest directly on grade. Precautions should be taken to prevent ground freezing under refrigerated tanks, as this can

cause the ground to heave and damage the foundation or the tank. Designing for free air circulation under the tank is a method for passive protection from ground freezing.

Steels lose their ductility at low temperatures and can become subject to brittle failure. There are specific requirements for metals to be used for refrigerated storage tanks in API 620, Appendices Q and R.

Corrosive chemicals and external exposure can cause tank failure. Materials of construction should be chosen so that they are compatible with the chemicals and exposure involved. Welding reduces the corrosion resistance of many alloys, leading to localized attack at the heat-affected zones. This may be prevented by the use of the proper alloys and weld materials, in some cases combined with annealing heat treatment.

External corrosion can occur under insulation, especially if the weather barrier is not maintained or if the tank is operating at conditions at which condensation is likely. This form of attack is hidden and may be unnoticed for a long time. Inspection holes and plugs should be installed in the insulation to monitor possible corrosion under the insulation.

**Pressure Vessels (above 15 psig)** The design of vessels above 15 psig falls within the scope of the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code, Section VIII, "Pressure Vessels, Division I," and should be designated as lethal service if required. *Lethal service* means containing substances that are "poisonous gases or liquids of such a nature that a very small amount of the gas or vapor of the liquid mixed or unmixed with air is dangerous to life when inhaled. This class includes substances which are stored under pressure or may generate a pressure if stored in a closed vessel." This is similar to, but not exactly the same as, the same definition as that for "Category M" fluid service of the ASME Pressure Piping Code (see below). Pressure vessels for the storage of highly hazardous materials should be designed in accordance with requirements of the ASME code even if the vessels could be exempted because of high pressure or size. The code requires that the corrosion allowance be adequate to compensate for the more or less uniform corrosion expected to take place during the life of the vessel and not weaken the vessel below design strength.

**Venting and Drainage** Low-pressure storage tanks are particularly susceptible to damage if good venting practices are not followed. A vent that does not function properly at all times may cause damage to the tank from pressure that is too high or too low. Vapors should go to a collection system, if necessary, to contain toxic and hazardous vents.

**Piping** Piping systems for toxic fluids fall within Chapter VIII of the ASME Pressure Piping Code, "Piping for Category M Fluid Service." Category M fluid service is defined as "fluid service in which the potential for personnel exposure is judged to be significant and in which a single exposure to a small quantity of a toxic fluid, caused by leakage, can produce serious irreversible harm to persons on breathing or bodily contact, even when prompt restorative measures are taken."

Piping systems should meet the requirements for both Category M fluid service and for "severe cyclic conditions." Piping systems should be subjected to a flexibility analysis, and if they are found to be too rigid, flexibility should be added. Severe vibration pulsations should be eliminated. Expansion bellows, flexible connections, and glass equipment should be avoided. Pipelines should be designed with the minimum number of joints, fittings, and valves. Joints should be flanged or butt-welded. Threaded joints should not be used.

**Instrumentation** (CCPS, 1986.) Instrument systems are an essential part of the safe design and operation of systems for storing and handling hazardous materials. They are key elements of systems to eliminate the threat of conditions that could result in loss of containment. They are also used for early detection of releases so that mitigating action can be taken before these releases result in serious effects on people in the plant or in the public sector, or on the environment.

**Pumps and Gaskets** The most common maintenance problem with centrifugal pumps is with the seals. Mechanical seal problems account for most of the pump repairs in a chemical plant, with bearing failures a distant second. The absence of an external motor (on canned pumps) and a seal is appealing to those experienced with mechanical seal pumps.

Sealless pumps are very popular and are widely used in the chemical industry. Sealless pumps are manufactured in two basic types: canned-motor and magnetic-drive. Magnetic-drive pumps have thicker "cans," which hold in the process fluid, and the clearances between the internal rotor and can are greater compared to canned-motor pumps. This permits greater bearing wear before the rotor starts wearing through the can. Many magnetic-drive pump designs now have incorporated a safety clearance, which uses a rub ring or a wear ring to support the rotating member in the event of excessive bearing wear or failure. This design feature prevents the rotating member (outer magnet holder or internal rotating shaft assembly) from accidentally rupturing the can, as well as providing a temporary bearing surface until the problem bearings can be replaced. Because most magnetic-drive pumps use permanent magnets for both the internal and external rotors, there is less heat to the pumped fluid than with canned-motor pumps. Some canned-motor pumps have fully pressure-rated outer shells, which enclose the canned motor; others do not. With magnetic-drive pumps, containment of leakage through the can to the outer shell can be a problem. Even though the shell may be thick and capable of holding high pressures, there is often an elastomeric lip seal on the outer magnetic rotor shaft with little pressure containment capability.

Canned-motor pumps typically have a clearance between the rotor and the containment shell or can, which separates the fluid from the stator, of only 0.008 to 0.010 in (0.20 to 0.25 mm). The can has to be thin to allow magnetic flux to flow to the rotor. It is typically 0.010 to 0.015 in (0.25 to 0.38 mm) thick and made of Hastelloy. The rotor can wear through the can very rapidly if the rotor bearing wears enough to cause the rotor to move slightly and begin to rub against the can. The can may rupture, causing uncontrollable loss of the fluid being pumped.

It should not be assumed that just because there is no seal, sealless pumps are always safer than pumps with seals, even with the advanced technology now available in sealless pumps. Use sealless pumps with considerable caution when handling hazardous or flammable liquids.

Sealless pumps rely on the process fluid to lubricate the bearings. If the wear rate of the bearings in the fluid being handled is not known, the bearings can wear unexpectedly, causing rupture of the can.

Running a sealless pump dry can cause complete failure. If there is cavitation in the pump, hydraulic balancing in the pump no longer functions and excessive wear can occur, leading to failure of the can. *The most common problem with sealless pumps is bearing failure, which occurs either by flashing the fluid in the magnet area because of a drop in flow below minimum flow or by flashing in the impeller eye as it leaves the magnet area.* It is estimated that 9 out of 10 conventional canned-motor pump failures are the result of dry running. Canned pumps are available which, their manufacturer claims, can be operated dry for as long as 48 h.

It is especially important to avoid deadheading a sealless pump. Deadheaded sealless pumps can cause overheating. The bearings may be damaged, and the pump may be overpressurized. The pump and piping systems should be designed to avoid dead spots when pumping monomers. Monomers in dead spots may polymerize and plug the pump. There are minimum flow requirements for sealless pumps. It is recommended that a recirculation system be used to provide internal pump flow whenever the pump operates. Inlet line filters are recommended, but care must be taken not to cause excessive pressure drop on the suction side. Typical inlet filters use sieve openings of 0.0059 in (0.149 mm).

A mistreated sealless pump can rupture with potentially serious results. The can can fail if valves on both sides of the pump are closed and the fluid in the pump expands, either due to heating up from a cold condition or if the pump is started up. If the pump is run dry, the bearings can be ruined. The pump can heat up and be damaged if there is insufficient flow to take away heat from the windings. Sealless pumps, especially canned-motor pumps, produce a significant amount of heat, since nearly all the electric energy lost in the system is absorbed by the fluid being pumped. *If this heat cannot be properly dissipated, the fluid will heat up with possibly severe consequences.* Considerable care must be used when installing a sealless pump to be sure that improper operations cannot occur.

The instrumentation recommended for sealless pumps may seem somewhat excessive. However, sealless pumps are expensive, and they

can be made to last for a long time, compared to conventional centrifugal pumps where seals may need to be changed frequently. Most failures of sealless pumps are caused by running them dry and damaging the bearings. Close monitoring of temperature is necessary in sealless pumps. Three temperature sensors (resistance temperature devices, or RTDs) are recommended: (1) in the internal fluid circulation loop, (2) in the magnet, or shroud, area, and (3) in the pump case area.

It is very important that sealless pumps be flooded with liquid before starting, to avoid damage to bearings from imbalance or overheating. Entrained gases in the suction can cause immediate imbalance problems and lead to internal bearing damage. Some type of liquid sensor is recommended. Sealless pumps must not be operated deadheaded (pump liquid full with inlet and/or outlet valves closed). Properly installed and maintained, sealless pumps, both canned-motor and magnetic-drive, offer an economical and safe way to minimize hazards and leaks of hazardous liquids.

**Loss-of-Containment Causes** The list in Table 23-30 indicates four basic ways in which containment can be lost. These cause categories can be used both as a checklist of considerations during the design process and as a starting point for evaluating the adequacy of safeguards as part of a process hazard and risk analysis.

**Maintaining the Mechanical Integrity of the Primary Containment System** The second main category in the above list pertains to containment failure under design operating conditions due to imperfections in the equipment. This group of causes is the main focus of a facility's mechanical integrity (MI) program. The MI program should also detect other imperfections such as previous periods

**TABLE 23-30 Summary of Loss-of-Containment Causes in the Chemical Industry**

|  |
|--|
| <b>I. Containment lost via an "open-end" route to atmosphere</b>   |
| A. Due to genuine process relief or dumping requirements   |
| B. Due to maloperation of equipment in service; e.g., spurious relief valve operation  |
| C. Due to operator error; e.g., drain or vent valve left open, misrouting of materials, tank overfilled, unit opened up under pressure   |
| <b>II. Containment failure under design operating conditions due to imperfections in the equipment</b>   |
| A. Imperfections arising prior to commissioning and not detected before start-up   |
| B. Imperfections due to equipment deterioration in service and not detected before the effect becomes significant  |
| C. Imperfections arising from routine maintenance or minor modifications not carried out correctly, e.g., poor workmanship, wrong materials  |
| <b>III. Containment failure under design operating conditions due to external causes</b>   |
| A. Impact damage, such as by cranes, road vehicles, excavators, machinery associated with the process  |
| B. Damage by confined explosions due to accumulation and ignition of flammable mixtures arising from small process leaks, e.g., flammable gas buildup in analyzer houses, in enclosed drains, around submerged tanks |
| C. Settlement of structural supports due to geologic or climatic factors or failure of structural supports due to corrosion, etc.  |
| D. Damage to tank trucks, railcars, containers, etc., during transport of materials on- or off-site  |
| E. Fire exposure   |
| F. Blast effects from a nearby explosion (unconfined vapor cloud explosion, bursting vessel, etc.), such as blast overpressure, projectiles, structural damage   |
| G. Natural events (acts of God) such as windstorms, earthquakes, floods, lightning   |
| <b>IV. Containment failure due to deviations in plant conditions beyond design limits</b>  |
| A. Overpressurizing of equipment   |
| B. Underpressurizing of non-vacuum-rated equipment   |
| C. High metal temperature (causing loss of strength)   |
| D. Low metal temperature (causing cold embrittlement and overstressing)  |
| E. Wrong process materials or abnormal impurities (causing accelerated corrosion, chemical attack of seals or gaskets, stress corrosion cracking, embrittlement, etc.)   |

SOURCE: Summarized from Appendix A of Prugh and Johnson, *Guidelines for Vapor Release Mitigation*, CCPS-AIChE, New York, 1988.

of operating outside design limits, or improper process materials or impurities that cause accelerated corrosion, chemical attack of seals or gaskets, stress corrosion cracking, embrittlement, etc. MI programs include quality assurance of the initial construction and of maintenance materials; routine preventive maintenance activities; regular inspections and nondestructive testing (NDT) of vessels, tanks, and piping to detect corrosion, pitting, erosion, cracking, creep, etc.; functional testing of standby equipment including alarms, safety instrumented systems, and emergency relief systems; and correcting problems that are identified while inspecting, testing, or maintaining the equipment and instrumentation. CCPS (2006) provides guidance on developing and implementing a mechanical integrity program.

**Release Detection and Mitigation** Mitigation means reducing the severity of consequences of an emergency situation such as a major release, fire, and/or explosion. The choice of mitigation strategies will depend on the nature of the hazardous materials and energies that can be released and the degree to which risk reduction is needed to ensure people, property, and the environment are adequately protected. The latter will be affected by the proximity of populations and sensitive environments surrounding the facility. An unstaffed remote natural gas facility will obviously not warrant the same mitigation measures as a facility using large quantities of high-toxic-hazard materials with other industry or residences nearby.

- To be effective, a mitigation strategy will need to be capable of
- Detecting either an incipient or an actual emergency situation
  - Deciding on and initiating the proper course of action to mitigate the situation
  - Reducing the severity of consequences at the source, in transit, and/or at the receptor locations
  - Preventing domino effects that could have even more severe consequences

Each of these steps might be performed either by direct action of operations or emergency response personnel or by automatic systems. An example of the latter might be an array of toxic or flammable gas detectors that might trip an emergency shutdown system that closes remotely actuated block valves and vents off the process pressure to a flare if two adjacent sensors read above a predetermined vapor concentration.

Mitigation measures can also be *passive* safeguards, meaning that they require no human intervention and no engineered sensing and actuation system to work. Examples of passive mitigation measures are secondary containment systems, blast-resistant and fire-resistant structures, insulated or low-heat-capacity spill surfaces to reduce the rate of evaporation, and an increased distance between the hazardous materials and energies and the sensitive receptors.

## Glossary

**Basic process control system (BPCS)** System that responds to input signals from the process, its associated equipment, other programmable systems, and/or an operator and generates output signals,

causing the process and its associated equipment to operate in the desired manner. The BPCS is commonly referred to as the *control system*.

**Compensating measures** Planned means for managing process risk during periods of process operation with known faults or problems that increase risk.

**Control layer** Protection layer that is used to maintain the process within the normal operating limits, such as standard operating procedures, basic process control system, and process alarms.

**Core attribute** Fundamental underlying property of a protection layer. The core attributes are independence, functionality, integrity, reliability, auditability, management of change, and access security.

**Independent protection layer** An IPL is a device, system, or action that is capable of preventing a hazard scenario from proceeding to the undesired consequence regardless of the initiating cause occurrence (or its consequences) or the failure of any other protection layer.

**Safety instrumented function (SIF)** A safety function allocated to the safety instrumented system with a safety integrity level necessary to achieve the desired risk reduction for an identified process hazard.

**Safety instrumented system (SIS)** Any combination of separate and independent devices (sensors, logic solvers, final elements, and support systems) designed and managed to achieve a specified safety integrity level. An SIS may implement one or more safety instrumented functions.

**Safety integrity level (SIL)** Discrete level (one out of a possible four SIL categories) used to specify the probability that a safety instrumented function will perform its required function under all operational states within a specified time.

**Introduction** The chemical processing industry relies on many types of instrumented systems, e.g., the basic process control systems (BPCSs) and safety instrumented system (SIS). The BPCS controls the process on a continuous basis to maintain it within prescribed control limits. Operators supervise the process and, when necessary, take action on the process through the BPCS or other independent operator interface. The SIS detects the existence of unacceptable process conditions and takes action on the process to bring it to a safe state. In the past, these systems have also been called emergency shutdown systems, safety interlock systems, and safety critical systems.

In 1993, the Center for Chemical Process Safety (CCPS) published *Guidelines for Safe Automation of Chemical Processes* (referred to henceforth as *Safe Automation*). *Safe Automation* provides guidelines for the application of automation systems used to control and shut down chemical and petrochemical processes. The popularity of one of the hazard and risk analysis methods presented in *Safe Automation* led to the publication of the 2001 Concept Series book from CCPS, *Layer of Protection Analysis: A Simplified Risk Assessment Approach*. This method builds upon traditional process hazards analysis techniques. It uses a semiquantitative approach to define the required performance for each identified protective system.

The Instrumentation, Systems, and Automation Society (ISA) published the Standard ANSI/ISA 84.01-1996, documenting the good engineering practice for the design, operation, maintenance, and testing of SIS. The standard established a numerical benchmark for the SIS performance known as the safety integrity level (SIL) and provided requirements on how to design and manage the SIS to achieve the target SIL.

*Safe Automation* and ANSI/ISA 84.01-1996 served as significant technical references for the first international standard, IEC 61511, issued by the International Electrotechnical Commission (IEC). In the United States, IEC 61511 was accepted by ISA as ISA 84.00.01-2004, replacing the 1996 standard. In 2004, the European Committee for Electrotechnical Standardization (CENELEC) and the American National Standards Institute (ANSI) recognized IEC 61511 as a consensus standard for the process industry. IEC 61511 covers the complete process safety management life cycle. With its adoption, this standard serves as the primary driving force behind the work processes followed to achieve and maintain safe operation using safety instrumented systems.

It is important that personnel understand how to achieve safe operation, but not at the exclusion of other important considerations, such as reliability, operability, and maintainability. The chemical industry has also found significant benefit to plant productivity and operability when SIS work processes are used to design and manage other instrumented protective systems (IPS), such as those mitigating potential economic and business losses. The CCPS book (2007) *Guidelines for Safe and Reliable Instrumented Protective Systems* discusses the activities and quality control measures necessary to achieve safe and reliable operation throughout the IPS lifecycle.

**Hazard and Risk Analysis** Consideration should be given to identifying process hazards as early as possible in the process equipment design, so that measures can be taken to reduce or eliminate the hazards. Inherently safer design strategies, such as minimize, substitute, moderate, and simplify, should be implemented.

When it is no longer practical to reduce the risk further by process design modification, protection layers are used to mitigate the remaining process risk. IPLs must meet the necessary rigor associated with seven core attributes: independence, functionality, integrity, reliability, auditability, access security, and management of change. There are two critical activities to be completed during the risk assessment phase. First, the safety functions (i.e., those functions that detect and respond to process hazards) are identified by using an accepted hazard and risk analysis (H&RA) methodology. Second, each safety function is allocated to a protection layer that is designed and managed to achieve the required risk reduction.

An H&RA involves a review of the process design and its control, operation, and maintenance practices. The review is conducted by a multidisciplinary team with expertise in the design and operation of the process unit. The team uses a systematic screening process to determine how deviations from normal operation lead to process hazards. The H&RA identifies areas where the process risk is too high, requiring the implementation of safety functions. The team's objective is to reduce the risk to below the owner/operator's risk criteria.

Process risk is defined by the frequency of the occurrence and the potential consequence severity of the process hazard. To define the frequency, the initiating causes (e.g., single causes or multiple causes and conditions) are identified for each process hazard, and their frequency of occurrence is estimated. The consequence severity is the logical conclusion to the propagation of the process hazard if no protection layers are implemented as barriers to the event.

The gap between the process risk and the owner/operator's risk criteria establishes the requirements for risk reduction. The risk gap can be managed by a single safety function or by multiple functions allocated to protection layers. The team defines the risk reduction that must be provided by each safety function and allocates the safety function to a protection layer that is designed and managed to achieve the allocated risk reduction.

When the safety function is allocated to the SIS, it is a safety instrumented function (SIF). The risk reduction allocated to the SIF defines its target safety integrity level (SIL). This target is related to the SIF probability of failure on demand (PFD), e.g., SIL 1 (PFD range: 0.01 to 0.1), SIL 2 (PFD range: 0.001 to 0.01), SIL 3 (PFD range: 0.0001 to 0.001), and SIL 4 (PFD range: 0.00001 to 0.0001).

The identification of safety functions continues until the process risk associated with the hazard is reduced to meet the risk criteria. When there is insufficient risk reduction provided by the current or planned design, the team makes recommendations for process design changes (e.g., inherently safer design), improvement to existing functions, or the design and implementation of new functions. These recommendations are generally prioritized based on the magnitude of the gap between the mitigated process risk (i.e., risk considering the presence of existing functions) and the risk criteria.

**Design Basis** In the design phase, the project team works together to create an SIS design basis that achieves the risk reduction strategy established in the risk reduction phase. This strategy relies, in part, on the implementation of SIFs to address identified process risk. The SIF uses dedicated devices, including process sensors that detect the process hazard, a logic solver that decides what to do, and final elements that take action on the process. Often, a single logic solver

implements multiple SIFs, so the potential for common-cause failures between SIFs should be considered during design.

The SIS is normally designed to fail-safe on loss of power and takes action only when the process demands that it do so. These demands often occur when safe operating limits are exceeded due to BPCS failures. Therefore, the SIS is designed and managed to be independent of the BPCS in terms of its hardware and software and its user interfaces, such as operator, maintenance, and engineering interfaces.

Systematic errors can occur anywhere in the design and implementation process or during the operational life of an SIS device. These errors put the SIS on the path to failure in spite of the design elements incorporated to achieve robust hardware and software systems. Systematic errors are minimized using work processes that address potential human errors in the SIS design and management (e.g., programming errors or hardware specification errors).

Random hardware failure can occur throughout the device life as components age in the environmental conditions of the process unit. These failures can cause a device to fail dangerously; i.e., it cannot perform as required. These failures are estimated by examining the dangerous failure modes of each device and their frequency of occurrence. The resulting failure rate is used to estimate the PFD of the SIS considering its specific devices, redundancy, diagnostics, common-cause failure potential, and proof test interval. The PFD is then compared to the target SIL assigned during the risk assessment phase to determine whether the design is adequate.

The design basis includes the process requirements specification and the safety requirements specification. The process requirements specification is typically developed by process engineering, with input from operations personnel. The process requirements are provided to the instrumentation, electrical, or controls systems personnel to develop the safety requirements specification with input from operations and maintenance personnel.

**Process Requirements Specification** Process engineering uses the H&RA findings, process design information, and operations input to

- Define safe state, including safety and nonsafety actions.
- Define reliability requirements necessary to achieve desired process unit uptime performance.
- Define operability requirements for modes of operation, such as start-up, reduced rates, maintenance modes, and shutdown.
- Identify windows of opportunity for SIS testing.
- Define process-related parameters.
- Define human-related parameters.

Guidance can be found in the CCPS book (2007) *Guidelines for Safe and Reliable Instrumented Protective Systems* related to the development of the process requirements specification.

**Safety Requirements Specification** The instrumentation and electrical (I&E) requirements are developed to meet the intent of any H&RA findings and the process requirements. The design documentation should establish a clear connection between each process hazard and the design of its SIFs. I&E personnel should meet with the process engineering representative responsible for the process requirements to ensure that the intent is understood.

I&E design focuses on achieving the target SIL through careful selection of the devices (e.g., user approved for safety), use of redundancy, on-line diagnostics, and frequent proof testing. The ISA technical report TR84.00.04 gives extensive guidance on design requirements for the hardware and software systems used to implement the SIS. Application-specific standards by organizations such as American Society of Mechanical Engineers (ASME), American Petroleum Institute (API), and the National Fire Protection Association (NFPA) may provide additional requirements and guidance.

There is often quite a bit of give and take between the process requirements and I&E requirements in the early stages of the project. For example, the ideal process measurement may not be practical in the existing installation. At all times, it should be recognized that the goal of the design is to prevent the process hazard from propagating to an incident.

**Engineering, Installation, Commissioning, and Validation (EICV)** This phase involves the physical realization of the design basis, which is developed in response to process risk identified in an H&RA study. The bulk of the work in this phase is not a process

engineering effort. Detailed engineering, installation, and commissioning is generally an I&E function. However, this is where the assumptions and requirements developed by the process engineer are put into practice and validated.

Validation of the SIS functionality is performed as part of a site acceptance test (SAT). Validation involves a full functional test that demonstrates the SIS actually works in the real-world installation. It proves the SIS devices execute the logic according to the specification and ensures that the SIS and its devices interact as intended with other systems, such as the BPCS and operator interface. From a systematic error standpoint, the SAT also provides an opportunity for a first-pass validation of the procedures developed for the operating basis (see next subsection).

Pre-start-up Safety Review (PSSR) approval of the SIS establishes the point where the SIS design and construction is considered complete. All documentation should be formally updated to as-built status, incorporating any modifications made since the last formal drawing or document revision. Once the PSSR has approved the SIS for process unit start-up, formal management of change procedures should be followed to address proposed modification to the SIS or its associated documentation. Any deviation from the approved design basis should be reviewed and approved by appropriate parties prior to change implementation.

**Operating Basis** As the SIS engineering design nears completion, the resources and skills of plant operations should be considered. At some point, the SIS is turned over to operations and maintenance personnel, who must be trained on the new SIS and on their responsibilities. Consequently, thought should be given to the content and depth of the information that must be communicated to various personnel. This is especially important as the responsibility for the SIS transitions from the project team to operations and maintenance control.

The process engineer is responsible for defining the content of SIS operating procedures, which should cover SIS specific information (e.g., set points, SIS actions, and the hazard that is being prevented with SIS), the correct use of bypasses and resets, the operator response to SIS alarms and trips, when to execute a manual shutdown, and provisions for operation with detected faults (e.g., compensating measures). These procedures, along with analogous ones developed by maintenance and reliability engineering for maintenance activities, make up the backbone of the operating basis.

Since a device can fail at any time during its life, periodic proof tests are performed to demonstrate the functionality of the SIS. Proof tests are covered by operation and maintenance procedures that ensure that the test is done correctly, consistently, and safely and that the device is returned to a fully operational state after test. Each test serves as an opportunity for personnel to see the SIS in action and to validate the procedures associated with its operation.

Proof testing is required for all SISs. It is used to demonstrate that the devices are operating as specified and are maintained in "as good as new" condition. Failures found during testing indicate gaps in the mechanical integrity program, necessitating root-cause investigation and corrective action.

## SECURITY

**Definition of Terms** (American Petroleum Institute/National Petroleum Refiner's Association, *Security Vulnerability Assessment Methodology for the Petroleum Industry*, 2004.)

**Adversary** Any individual, group, organization, or government that conducts activities, or has the intention and capability to conduct activities detrimental to critical assets. An adversary could include intelligence services of host nations, or third-party nations, political and terrorist groups, criminals, rogue employees, and private interests. Adversaries can include site insiders, site outsiders, or the two acting in collusion.

**Alert levels** A progressive, qualitative measure of the likelihood of terrorist actions, from negligible to imminent, based on government or company intelligence information. Different security measures may be implemented at each alert level based on the level of threat to the facility.

**Asset** Any person, environment, facility, material, information, business reputation, or activity that has a positive value to an owner. The asset may have value to an adversary, as well as an owner, although

the nature and magnitude of those values may differ. Assets in the SVA include the community and the environment surrounding the site.

**Asset category** Assets may be categorized in many ways. Among these are by people, hazardous materials (used or produced), information, environment, equipment, facilities, activities and operations, and company reputation.

**Countermeasures** An action taken or a physical capability provided whose principal purpose is to reduce or eliminate one or more vulnerabilities. The countermeasure may also affect the threat(s) (intent and/or capability) as well as the asset's value. The cost of a countermeasure may be monetary, but may also include nonmonetary costs such as reduced operational effectiveness, adverse publicity, unfavorable working conditions, and political consequences.

**Cyber security** Protection of critical information systems including hardware, software, infrastructure, and data from loss, corruption, theft, or damage.

**Delay** A countermeasures strategy that is intended to provide various barriers to slow the progress of an adversary in penetrating a site, to prevent an attack or theft, or in leaving a restricted area to assist in apprehension and prevention of theft.

**Detection** A countermeasures strategy that is intended to identify an adversary attempting to commit a security event or other criminal activity in order to provide real-time observation as well as postincident analysis of the activities and identity of the adversary.

**Deterrence** A countermeasures strategy that is intended to prevent or discourage the occurrence of a breach of security by means of fear or doubt. Physical security systems such as warning signs, lights, uniformed guards, cameras, and bars are examples of countermeasures that provide deterrence.

**Hazard** A situation with the potential for harm.

**Intelligence** Information to characterize specific or general threats including the motivation, capabilities, and activities of adversaries.

**Intent** A course of action that an adversary intends to follow.

**Likelihood of adversary success (LAS)** The potential for causing a catastrophic event by defeating the countermeasures. LAS is an estimate that the security countermeasures will thwart or withstand the attempted attack, or if the attack will circumvent or exceed the existing security measures. This measure represents a surrogate for the conditional probability of success of the event.

**Physical security** Security systems and architectural features that are intended to improve protection. Examples include fencing, doors, gates, walls, turnstiles, locks, motion detectors, vehicle barriers, and hardened glass.

**Response** The act of reacting to detected or actual criminal activity either immediately following detection or after the incident.

**Risk** The potential for damage to or loss of an asset. Risk, in the context of process security, is the potential for a catastrophic outcome to be realized. Examples of the catastrophic outcomes that are typically of interest include an intentional release of hazardous materials to the atmosphere, or the theft of hazardous materials that could later be used as weapons, or the contamination of hazardous materials that may later harm the public, or the economic costs of the damage or disruption of a process.

**Risk assessment** Risk (R) assessment is the process of determining the likelihood of an adversary (T) successfully exploiting vulnerability (V) and the resulting degree of consequences (C) on an asset. A risk assessment provides the basis for rank-ordering risks and thus establishing priorities for the application of countermeasures.

**Security layers of protection** Also known as concentric "rings of protection," a concept of providing multiple independent and overlapping layers of protection in depth. For security purposes, this may include various layers of protection such as countersurveillance, counterintelligence, physical security, and cyber security.

**Security vulnerability assessment (SVA)** The process of determining the likelihood of an adversary successfully exploiting vulnerability, and the resulting degree of damage or impact. SVAs are not quantitative risk analyses, but are performed qualitatively using the best judgment of security and safety professionals. The determination of risk (qualitatively) is the desired outcome of the SVA, so that it provides the basis for rank ordering of the security-related risks and thus establishing priorities for the application of countermeasures.

**Target attractiveness** An estimate of the value of a target to an adversary based on the factors shown below. Experience has shown that, particularly for terrorist attacks, certain targets better accomplish the objectives of the adversaries than do others. Since the SVA is a risk-based analytical approach, consideration must be given to these factors in defining the threat and in determining the need for any enhanced countermeasures.

- Potential for mass casualties and fatalities
- Extensive property damage
- Proximity to national assets or landmarks
- Possible disruption or damage to critical infrastructure
- Disruption of the national, regional, or local economy
- Ease of access to target
- Media attention or possible interest of the media
- Company reputation and brand exposure

**Threat** Any indication, circumstance, or event with the potential to cause the loss of, or damage to, an asset. Threat can also be defined as the intention and capability of an adversary to undertake actions that would be detrimental to critical assets.

**Threat categories** Adversaries may be categorized as occurring from three general areas:

- Insiders
- Outsiders
- Insiders working in collusion with outsiders

**Vulnerability** Any weakness that can be exploited by an adversary to gain access to an asset. Vulnerabilities can include, but are not limited to, building characteristics; equipment properties; personnel behavior; locations of people, equipment, and buildings; or operational and personnel practices.

**Introduction** Prior to September 11, 2001, known as 9/11, chemical process safety activities primarily focused on accidental release risks and excluded most considerations of intentional releases. Security was provided mostly for lesser threats than such extreme acts of violence, and terrorism was generally not provided for except in high-security areas of the world. Exceptions to this included general concerns for sabotage. This was due to a perception that these risks were managed adequately, and that the threat of a terrorist attack, particularly on U.S. chemical manufacturing facilities or transportation system, was remote.

Following 9/11 it became apparent that the threat of intentional harm to infrastructure, especially where hazardous materials were manufactured, stored, processed, or transported, had to be considered a credible concern. Security for the chemical industry took on increased emphasis as a result, and such organizations as the American Institute of Chemical Engineers recognized the paradigm shift and published guidelines on analyzing these threats.<sup>o</sup> The concerns of international terrorism have spread to many countries around the world, and addressing this concern is now a permanent part of the requirements of the chemical engineering profession. Chemical engineers now must include *chemical process security* as a critical element of the management of a process facility.

Chemical process security management has as its objectives

1. To minimize the risk of harm to the public or employees from intentional acts against a process facility
2. To protect the assets (including employees) of the process facility to maintain the ongoing integrity of the operation and to preserve the value of the investment

Process security and process safety have many parallels and use many common programs and systems for achieving their ends. Process security management requires a systems approach to develop a comprehensive security program, which shares many common elements with process safety management.

Chemical process security includes, but goes beyond, traditional *physical security*. Physical security includes such considerations as guards, barriers, surveillance equipment, and other physical system considerations. Physical security is an element of chemical process security, but physical security alone is not always adequate to address the new challenges of security against extreme acts of violence, such as terrorism.

<sup>o</sup>Guidelines for Managing and Analyzing the Security Vulnerabilities of Fixed Chemical Sites, American Institute of Chemical Engineers, August 2002.

Effective chemical process security must also consider integration of broader process elements including technology, chemical usage and quantities, procedures, administrative controls, training, and cyber interface with those traditional physical security elements.

The chemical engineer has an opportunity to influence these considerations in all stages of a process life cycle, including concept, engineering, construction, commissioning, operations, modification, and decommissioning. Security issues that are recognized in the concept and design phases of a project may allow for cost-effective considerations that can eliminate or greatly minimize security risks. For example, if a buffer zone can be provided between the public areas and a plant fence, and then again between a plant fence and critical process equipment, those two zones can effectively provide such benefits as

- *Detection zone(s)*, given they are free of obstacles and have sufficient depth to allow for adversaries to be detected while attempting unlawful entry
- *Standoff zone(s)*, given they have sufficient depth to keep adversaries from using explosives or standoff weapons effectively from the perimeter
- *Delay zone(s)* allowing intervening force the time to respond or time for operators to take evasive action before an adversary reaches a target following detection

A chemical engineer may have a choice of inherent safety variables, such as quantity stored or process temperatures and pressures, or process safety measures such as emergency isolation valves or containment systems, all of which may greatly reduce the vulnerabilities or the consequences of intentional loss. These are in addition to traditional security measures, which may include physical security, background checks, administrative controls, access controls, or other protective measures. For a more complete discussion of the options, refer to the AIChE Center for Chemical Process Safety *Guidelines for Analyzing and Managing the Security Vulnerabilities of Fixed Chemical Sites*<sup>6</sup> and other references.<sup>1</sup>

**Threats of Concern** Terrorist acts can be the most problematic to defend against since they may be more extreme or malevolent than other crimes focused on monetary gains or outcomes with less malicious intent. Plus terrorists may use military tactics not often provided for in base chemical facility design. Chemical facility security must be considered in context with local and national homeland security and law enforcement activities, as well as with emergency response capabilities. There is a practical limit to the ability of a chemical site to prevent or mitigate a terrorist act. Above a certain level of threat, the facility needs to rely on law enforcement and military services to provide physical security against extreme acts of intentional harm. The security posture must be risk-based, and so extremely robust security measures are not always applicable or necessary.

The acts of concern for terrorism can be generally defined as involving the four motives shown in Table 23-31.

Other adversaries that must be considered as applicable include those capable and interested in perpetrating a full spectrum of security acts. These may include outside parties or insiders or a combination of the two working in collusion.

The threats that are applicable and the adversaries that may be culpable are characterized to understand their capabilities, intent, and therefore potential targets and tactics. The targets and acts of interest to various adversaries will vary with the group. For example, a terrorist may be interested in destroying a process through violent means, such as by the use of an explosive device. An activist may be interested only in a nonviolent protest or in causing some limited physical damage, but not in harming the environment or the public in the process. The various

Healy, eds., *Protection of Assets Manual*, Merritt Co., Santa Monica, Calif. (four-volume loose-leaf reference manual, updated monthly).

**TABLE 23-31 Security Issues of Concern with Example Applications to Terrorism**

| Security motives of concern <sup>a</sup> | Example terrorist means and objectives  |
|--|---|
| Intentional loss of containment          | By causing a release of chemicals to the atmosphere and potential toxic release, fire, or explosion to harm the public, workers, or the environment, or to destroy the facility |
| Theft of chemicals                       | For their eventual reuse as primary or secondary improvised weapons against a third party   |
| Contamination or spoilage of a process   | To cause immediate or delayed harm to people or the environment, or to cause severe economic injury   |
| Degradation of the asset                 | By causing mechanical damage or physical or cyber disruption, for purposes of causing severe direct or indirect economic damages  |

<sup>a</sup>Adapted from *Guidelines for Managing and Analyzing the Security Vulnerabilities of Fixed Chemical Sites*, American Institute of Chemical Engineers, August 2002.

adversaries and strategies of interest form the basis of the vulnerability assessment, which is the foundation of a chemical process security management system specific to address the anticipated threats.

**Overall Objectives of Terrorism** Terrorists attempt to cause change to accomplish their goals by creating fear and uncertainty in the population they are targeting through the use of violent acts. The underlying goals include fundamentalist objectives, such as purity of religion or idealistic goals, but they may include power struggles, such as trying to overthrow a government, or reparations, such as revenge for past actions. The reason for a chemical plant being targeted may be that it serves an adversary of the terrorist (economic or military significance) or that it can be weaponized to cause third-party harm (health and safety consequences from intentional release of hazardous materials).

**Security Vulnerability Assessment** A security vulnerability assessment is intended to identify security vulnerabilities from a wide range of threats ranging from vandalism to terrorism. With the recognition of threats, consequences, and vulnerabilities, the risk of security events can be evaluated, and a security management system can be organized that will effectively mitigate those risks.

**SVA Methodologies** There are several SVA techniques and methods available to the industry, all of which share common elements. The following is a list of some available SVA methodologies published by various governments, private, and trade and professional organizations. Some are merely chapters or sections of documents that address security or risk assessment/risk management in broader terms. Some are SVA or VA publications by themselves. Some of these "methods" are complete, systematic analytical techniques, and others are mere checklists.

- American Institute of Chemical Engineers Center for Chemical Process Safety: *Guidelines for Analyzing and Managing the Security Vulnerabilities of Fixed Chemical Sites*, 2002.
- American Petroleum Institute/National Petroleum Refiner's Association, *Security Vulnerability Assessment Methodology for the Petroleum Industry*, 2003.
- National Institute of Justice, *Chemical Facility Vulnerability Assessment Methodology*, July 2002 (Sandia VAM).
- Synthetic Organic Chemical Manufacturers Association, Inc. (SOCMA), *Manual on Chemical Site Security Vulnerability Analysis Methodology and Model*, 2002.

One approach to conducting an SVA is shown in Fig. 23-64. This methodology was published by the American Institute of Chemical Engineers, Center for Chemical Process Safety, in 2002. The CCPS SVA is founded on a risk-based approach to managing chemical facility security. To begin the process, companies may perform an enterprise-level screening methodology to sort out significant risks among multiple sites and to determine priorities for analysis and implementation of any recommended changes. The screening, if performed, would result in a prioritized list of sites and forms the foundation of the choice of specific SVAs required. The book covers how to integrate chemical security

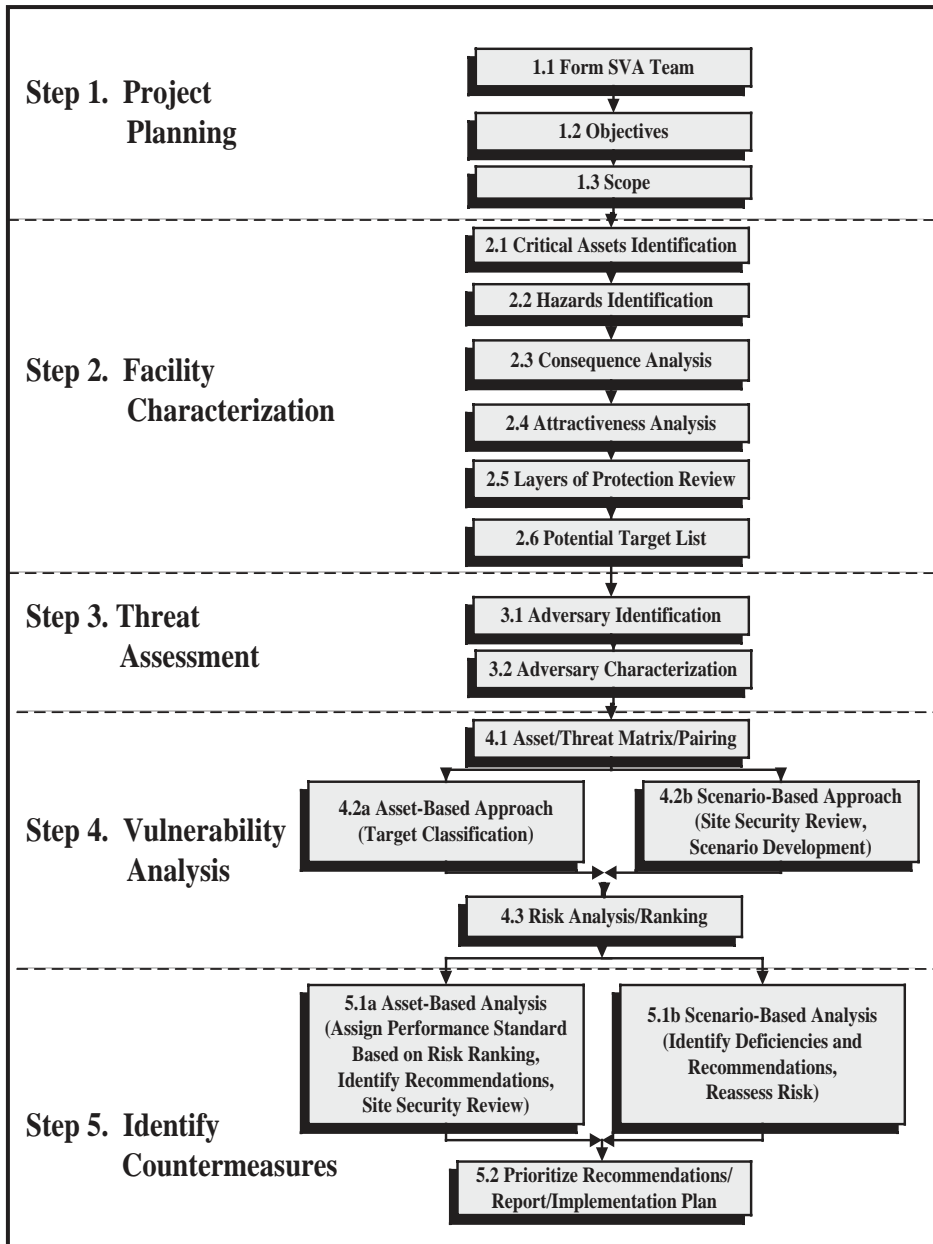

FIG. 23-64 CCPS SVA process.

management and process safety management strategies into a comprehensive process safety and security strategy. Security risk reduction opportunities during the process life cycle are explained, as well as various process risk management strategies (including inherent safety) that are applicable.

In the appendices, the book contains a set of tools including an enterprise-level screening tool, reference information available to conduct the CCPS SVA, and a workbook with worksheets for conducting the CCPS SVA, examples of enhanced security measures, and checklists for assessing security measures at a site.

**Defining the Risk to Be Managed** For the purposes of an SVA, the definition of risk is shown in Fig. 23-65. The risk that is being

analyzed for the SVA is defined as an expression of the likelihood that a defined threat will target and successfully attack a specific security vulnerability of a particular target or combination of targets to cause a given set of consequences. This is contrasted with the usual accidental risk definitions. The risk variables are defined as shown in Table 23-32.

A challenge for security vulnerability analysis is that the accurate prediction of the frequency and location of terrorist acts is not considered credible. As such, the analyst has a choice of assuming a frequency of a certain attack or assuming the attack frequency is 1, thereby focusing solely on the conditional likelihood of success of the adversary who attempts an attack. While the latter approach provides a baseline for making decisions about vulnerability, it does not fully

FIG. 23-65 Intentional release vs. accidental release.

answer the question of cost/benefit of any countermeasures. Certain crimes other than terrorism may be more predictable or frequent, allowing for statistical analysis to help frame the risks and justify countermeasure expenditures. Due to this limitation, the factor of attractiveness is considered along with consequences, threat, and vulnerability, to determine the priorities for and design of security measures for the industry.

**Security Strategies** A basic premise is that not all security risks can be completely prevented. Appropriate strategies for managing security can vary widely depending on the circumstances including the type of facility and the threats facing the facility. As a result, it is difficult to prescribe security measures that apply to all facilities in all industries. Instead, it is suggested to use the SVA as a means of identifying, analyzing, and reducing vulnerabilities. The specific situations must be evaluated individually by local management using best judgment of applicable practices. Appropriate security risk management decisions must be made commensurate with the risks. This flexible approach recognizes that there isn't a uniform approach to security in the chemical process industry, and that resources are best applied to mitigate high-risk situations primarily.

Security strategies for the process industries are generally based on the application of four key concepts against each threat: deterrence, detection, delay, and response.\*

\**Managing and Analyzing the Security Vulnerabilities of Fixed Chemical Sites*, AIChE, August 2002.

A complete security design includes these four concepts in layers of protection or a defense in depth arrangement. The most critical assets should be placed in the center of conceptual concentric levels of increasingly more stringent security measures. In the concept of rings of protection, the spatial relationship between the location of the target asset and the location of the physical countermeasures is important.

In the case of malicious acts, the layers or rings of protection must be particularly robust because the adversaries are intentionally attempting to breach the protective features and can be counted on to use whatever means are available to be successful. This could include explosions or other initiating events that result in widespread common-cause failures. Some particularly motivated adversaries might commit suicide while attempting to breach the security layers of protection.

**Countermeasures and Security Risk Management Concepts** Countermeasures are actions taken to reduce or eliminate one or more vulnerabilities. Countermeasures include hardware, technical systems, software, interdictive response, procedures, and administrative controls.

Security risk reduction at a site can include the following strategies:

- Physical security
- Cyber security
- Crisis management and emergency response plans
- Policies and procedures
- Information security
- Intelligence
- Inherent safety

TABLE 23-32 SVA Risk Variables

| Consequences          | Potential Impact of the Event  |
|-----------------------|--|
| Likelihood            | Likelihood is a function of the chance of being targeted for attack, and the conditional chance of mounting a successful attack (both planning and executing), given the threat and existing security measures. This is a function of three variables below. |
| Threat                | Threat, is a function of the adversary's existence, intent, motivation, capabilities, and known patterns of potential adversaries. Different adversaries may pose different threats to various assets within a given facility.                               |
| Vulnerability         | This is weakness that can be exploited by an adversary to gain access and damage or steal an asset or disrupt a critical function. This is a variable that indicates the likelihood of a successful attack, given the intent to attack an asset.             |
| Target attractiveness | Target attractiveness is a surrogate measure for likelihood of attack. This factor is a composite estimate of the perceived value of a target to the adversary and the adversary's degree of interest in attacking the target.                               |

\*Site Security Guidelines for the U.S. Chemical Industry, American Chemistry Council, October 2001.

**Security Management System** A comprehensive process security management system must include management program elements that integrate and work in concert with other management systems to control security risks. The 13 management practices shown in Table 23-33 are an example of a management system developed by the American Chemistry Council.

The purpose of a security management system is to ensure the ongoing, integrated, and systematic application of security principles and programs to protect personnel and assets in a dynamic security environment to ensure the continuity of the operation and supporting or dependent infrastructure. Traditional industrial facility security management tended to focus on protection of persons and property from crime (e.g., theft of property, workplace violence) and crime prevention, response, and investigation. While that is still an element of facility security, a management system allows incorporation of broader security concerns relating to intentional attack on fixed assets, such as by terrorists. To develop and implement a security management system not only provides a more thorough, dynamic, risk-based, and proactive approach, but also allows security management to be integrated into a facility's overall EH&S management systems.

The American Chemistry Council's Responsible Care® Security Code is designed to encourage continuous improvement in security performance by using a risk-based approach to identify, assess, and address vulnerabilities; prevent or mitigate incidents; enhance training and response capabilities; and maintain and improve relationships with key stakeholders. As a condition of membership in the council, each member company must implement the Security Code for facilities, transportation and value chain, and cyber security.

## KEY PROCEDURES

Safety by design should always be our aim but is often impossible or too expensive, and then we have to rely on procedures. Key features of all procedures are as follows:

- They should be as simple as possible and described in simple language, so as to help the reader rather than protect the writer.
- They should be explained to and discussed with those who will have to carry them out, not just sent to them through the post.
- Regular checks and audits should be made to confirm that they are being carried out correctly.

Many accidents have occurred because the three procedures discussed below were unsatisfactory or were not followed.

**Preparation of Equipment for Maintenance** The essential feature of this procedure is a permit-to-work system: The operating team members prepare the equipment and write down on the permit the work to be done, the preparation carried out, the remaining hazards, and the precautions necessary. The permit is then accepted by the person or group who will carry out the work and is returned when the work is complete. The permit system will not make maintenance 100 percent safe, but it reduces the chance that hazards will be overlooked, lists ways of controlling them, and informs those doing the job what precautions they should take. The

system should cover such matters as who is authorized to issue and accept permits-to-work, the training they should receive (not forgetting deputies), and the period of time for which permits are valid. It should also cover the following:

**Isolation of the Equipment under Maintenance** Poor or missing isolation has been the cause of many serious accidents. Do not rely on valves except for quick jobs; use blinds or disconnection and blanking unless the job is so quick that blinding (or disconnection) would take as long and be as hazardous as the main job. Valves used for isolation (including isolation while fitting blinds or disconnecting) should be locked shut (e.g., by a padlock and chain). Blinds should be made to the same standard (pressure rating and material of construction) as the plant. Plants should be designed so that blinds can be inserted without difficulty; i.e., there should be sufficient flexibility in the pipework, or a slip-ring or figure 8 plate should be used. Electricity should be isolated by locking off or removal of fuses. Do not leave the fuses lying around for anyone to replace. Always try out electrical equipment after defusing to check that the correct fuses have been withdrawn.

**Identification of the Equipment** Many accidents have occurred because maintenance workers opened up the wrong equipment. Equipment that is under repair should be numbered or labeled unambiguously. Temporary labels should be used if there are no permanent ones. Pointing out the correct equipment is not sufficient. "The pump you repaired last week is leaking again" is a recipe for an accident.

**Freeing from Hazardous Materials** Equipment that is to be repaired should be freed as far as possible from hazardous materials. Gases can be removed by sweeping out with nitrogen (if the gases are flammable) or air; water-soluble liquids, by washing with water; and oils, by steaming. Some materials such as heavy oils and materials that polymerize are very difficult or impossible to remove completely. Tests should be carried out to make sure that the concentration of any hazardous material remaining is below an agreed level. Machinery should be in the lowest energy state. Thus the forks of fork lift trucks should be lowered, and springs should not be compressed or extended. For some machinery the lowest energy state is less obvious. Do not work under heavy suspended loads.

**Special Jobs** Certain jobs, such as entry to vessels and other confined spaces, hot work, and responsibilities of contractors, raise special problems.

**Handover** Permits should be handed over (and returned when the job is complete) person to person. They should not be left on the table for people to sign when they come in.

**Change of Intent** If there is a change in the work to be done, the permit should be returned and a new one issued (Crowl and Grossel, eds., *Handbook of Toxic Materials Handling and Management*, Marcel Dekker, 1994, Chap. 12).

**Control of Modifications to Plants, Processes, and Organization** Many accidents have occurred when such modifications had unforeseen and unsafe side effects (Sanders, *Chemical Process Safety Learning from Case Histories*, 3d ed., Gulf Professional, 2005). No such modifications should therefore be made until they have been authorized by a professionally qualified person who has made a systematic attempt to identify and assess the consequences of the proposal, by hazard and operability study or a similar technique. When the modification is complete, the person who authorized it should inspect it to make sure that the design intention has been followed and that it "looks right." What does not look right is usually wrong and should at least be checked.

- Unauthorized modifications are particularly liable to occur
- During start-ups, as changes may be necessary to get the plant on-line.
  - During maintenance, as the maintenance workers may be tempted to improve the plant as well as repair it. They may suggest modifications, but should put the plant back as it was unless a change has been authorized.
  - When the modification is cheap and no financial authorization is necessary. Many seemingly trivial modifications have had tragic results.
  - When the modification is temporary. Twenty-eight people were killed by the temporary modification at Flixborough, one of the

most famous of all time (Mannan, *Lees' Loss Prevention in the Process Industries*, 3d ed., Elsevier, Amsterdam, 2005, Appendix A1; Kletz, *Learning from Accidents*, 3d ed., Gulf Professional, Boston, 2001, Chap.8).

- When one modification leads to another, and then another (Kletz, *Plant/Operations Progress*, vol. 5, 1986, p. 136).
- When organizations are changed often, especially when staffing is reduced. Such changes should be studied as thoroughly as changes to equipment or processes.

**Inspection and Testing of Protective Equipment** All protective equipment should be scheduled for regular inspection and for testing if failure is latent (hidden); e.g., we do not know if an interlock, trip, alarm, or relief valve is in working order unless we test it. The frequency of testing or inspection depends on the failure rate and the length of time considered tolerable if it fails. Relief valves fail about once per 100 years on average, and testing every 1 or 2 years is usually adequate. Protective systems based on instruments, such as trips and alarms, fail more often, about once every couple of years on average; so more frequent testing is necessary, about once per month. Pressure systems (vessels and pipework) on noncorrosive duties can go for many years between inspections, but on some duties they may have to be inspected annually or even more often.

All protective equipment should be designed so that it can be tested or inspected, and access should be provided. Audits should include a check that the tests are carried out and the results acted on.

The supervisor, manager, or engineer responsible should be reminded when a test or inspection is due, and senior managers should be informed if it has not been carried out by the due date. Test and inspection schedules should include guidance on the methods to be used and the features that should be inspected. For example, if the time of response is critical, it should be checked.

Test results should be displayed for all to see, e.g., on a board in the control room.

Tests should be like real life. For example, a high-temperature trip failed to work despite regular testing. It was removed from its case before testing so the test did not disclose that the pointer rubbed against the case. This prevented it from indicating a high temperature.

Operators sometimes regard tests and inspections as a nuisance, interfering with the smooth operation of the plant. Operator training should emphasize that protective equipment is there for their protection and they should "own" it.

**Key Performance Indicators** Preparation for maintenance, the control of modifications, and the testing of protective equipment are examples of key performance indicators; i.e., taken together, they indicate the quality of the plant's and company's process safety. If they are below standard, the plant is at risk. The usual measure of safety, the lost-time accident (LTA) rate, does not measure process safety. Many companies that had a low LTA rate and assumed that their process safety was therefore under control have experienced serious fires and explosions.

Turner, *Energy Management Handbook* 5th ed., The Fairmont Press, Lilburn, Ga., 2004. *National Energy Policy*, National Energy Policy Development Group, Washington, May 2001.

*Energy* is usually defined as the capacity to do work. Nature provides us with numerous sources of energy, some difficult to utilize efficiently (e.g., solar radiation and wind energy), others more concentrated or energy dense and therefore easier to utilize (e.g., fossil fuels). Energy sources can be classified also as *renewable* (solar and nonsolar) and *nonrenewable*. Renewable energy resources are derived in a number of ways: gravitational forces of the sun and moon, which create the tides; the rotation of the earth combined with solar energy, which generates the currents in the ocean and the winds; the decay of radioactive minerals and the interior heat of the earth, which provide geothermal energy; photosynthetic production of organic matter; and the direct heat of the sun. These energy sources are called renewable because they are either continuously replenished or, for all practical purposes, are inexhaustible.

Nonrenewable energy sources include the fossil fuels (natural gas, petroleum, shale oil, coal, and peat) as well as uranium. Fossil fuels are both energy dense and widespread, and much of the world's industrial, utility, and transportation sectors rely on the energy contained in them. Concerns over global warming notwithstanding, fossil fuels will remain the dominant fuel form for the foreseeable future. This is so for two reasons: (1) the development and deployment of new technologies able to utilize renewable energy sources such as solar, wind, and biomass are uneconomic at present, in most part owing to the diffuse or intermittent nature of the sources; and (2) concerns persist over storage and/or disposal of spent nuclear fuel and nuclear proliferation.

Fossil fuels, therefore, remain the focus of this section; their principal use is in the generation of heat and electricity in the industrial, utility, and commercial sectors, and in the generation of shaft power in transportation. The material in this section deals primarily with the conversion of the chemical energy contained in fossil fuels to heat and electricity. Material from *Perry's Chemical Engineers' Handbook*, 7th ed., Sec. 27, has been updated and condensed. Recent improvements in materials and manufacturing methods have brought fuel cells closer to being economic for stationary and transportation power generation, but additional advances are required for broad adoption.

## FUELS

## RESOURCES AND RESERVES

Proven worldwide energy resources are large. The largest remaining known reserves of crude oil, used mainly for producing transportation fuels, are located in the Middle East, along the equator, and in the former Soviet Union. U.S. proven oil reserves currently account for only about 3 percent of the world's total. Large reserves of natural gas exist in the former Soviet Union and the Middle East. Coal is the most abundant fuel on earth and the primary fuel for electricity in the United States, which has the largest proven reserves. Annual world consumption of energy is still currently less than 1 percent of combined world reserves of fossil fuels. The resources and reserves of the principal fossil fuels in the United States—coal, petroleum, and natural gas—follow.

| Fuel        | ZJ*             |  |                          |
|-------------|-----------------|--|--------------------------|
|             | Proven reserves | Discovered conventionally reservoiried | Total estimated resource |
| Coal        | 6.48            | 12.5                                   | 96.2                     |
| Petroleum   | 0.16            | 0.5                                    | 1.2                      |
| Natural gas | 0.21            | 0.4                                    | 1.6                      |

\*ZJ = 10<sup>21</sup> J. (To convert to 10<sup>18</sup> Btu, multiply by 0.948.)

The energy content of fossil fuels in commonly measured quantities is as follows.

|                                | Energy content         |                                 |
|--------------------------------|------------------------|---------------------------------|
| Bituminous and anthracite coal | 30.2 MJ/kg             | 26 × 10 <sup>6</sup> Btu/US ton |
| Lignite and subbituminous coal | 23.2 MJ/kg             | 20 × 10 <sup>6</sup> Btu/US ton |
| Crude oil                      | 38.5 MJ/L              | 5.8 × 10 <sup>6</sup> Btu/bbl   |
| Natural-gas liquids            | 25.2 MJ/L              | 3.8 × 10 <sup>6</sup> Btu/bbl   |
| Natural gas                    | 38.4 MJ/m <sup>3</sup> | 1032 Btu/ft <sup>3</sup>        |

1 bbl = 42 US gal = 159 L = 0.159 m<sup>3</sup>

## SOLID FUELS

## Coal

**GENERAL REFERENCES:** Lowry (ed.), *Chemistry of Coal Utilization*, Wiley, New York, 1945; suppl. vol., 1963; 2d suppl. vol., Elliott (ed.), 1981. Van Krevelen, *Coal*, Elsevier, Amsterdam, 1961. *Annual Book of ASTM Standards*, sec. 5, ASTM International, West Conshohocken, Pa., 2004. *Methods of Analyzing and Testing Coal and Coke*, U.S. Bureau of Mines Bulletin, 638, 1967.

**Origin** Coal originated from the arrested decay of the remains of trees, bushes, ferns, mosses, vines, and other forms of plant life, which flourished in huge swamps and bogs many millions of years ago during prolonged periods of humid, tropical climate and abundant rainfall. The precursor of coal was peat, which was formed by bacterial and chemical action on the plant debris. Subsequent actions of heat, pressure, and other physical phenomena metamorphosed the peat to the various ranks of coal as we know them today. Because of the various degrees of the metamorphic changes during this process, coal is not a uniform substance; no two coals are ever the same in every respect.

**Classification** Coals are classified by rank, i.e., according to the degree of metamorphism in the series from lignite to anthracite. Table 24-1 shows the classification system described in ASTM D 388-99 (2004) (ASTM International, op. cit.). The heating value on the moist *mineral-matter-free* (mmf) basis, and the fixed carbon, on the dry mmf basis, are the bases of this system. The lower-rank coals are classified according to the heating value, kJ/kg (Btu/lb), on a moist mmf basis. The agglomerating character is used to differentiate between adjacent groups. Coals are considered agglomerating if the coke button remaining from the test for volatile matter will support a specified weight or if the button swells or has a porous cell structure.

The Parr formulas, Eqs. (24-1) to (24-3), are used for classifying coals according to rank. The Parr formulas are employed in litigation cases.

$$F' = \frac{100(F - 0.15S)}{100 - (M + 1.08A + 0.55S)} \quad (24-1)$$

TABLE 24-1 Classification of Coals by Rank\*

| Class/group                     | Fixed carbon limits (dry, mineral-matter-free basis), % |           | Volatile matter limits (dry, mineral-matter-free basis), % |                    | Gross calorific value limits (moist, mineral-matter-free basis)† |           |                       |           | Agglomerating character |

Adapted, with permission, from D388-99, Standard Classification of Coals by Rank; copyright ASTM International, 100 Barr Harbor Drive, West Conshohocken, PA 19428.

\*This classification does not apply to certain coals, as discussed in source.

†Moist refers to coal containing its natural inherent moisture but not including visible water on the surface of the coal.

‡If agglomerating, classify in low-volatile group of the bituminous class.

§Coals having 69 percent or more fixed carbon on the dry, mineral-matter-free basis shall be classified according to fixed carbon, regardless of gross calorific value.

¶It is recognized that there may be nonagglomerating varieties in these groups of the bituminous class and that there are notable exceptions in the high-volatile C bituminous group.

$$V' = 100 - F' \tag{24-2}$$

$$Q' = \frac{100(Q - 50S)}{100 - (M + 1.08A + 0.55S)} \tag{24-3}$$

where *M*, *F*, *A*, and *S* are weight percentages, on a moist basis, of moisture, fixed carbon, ash, and sulfur, respectively; *Q* and *Q'* are calorific values (Btu/lb), on a moist non-mmf basis and a moist mmf basis, respectively. (Btu/lb = 2326 J/kg)

**Composition and Heating Value** Coal analyses are reported on several bases, and it is customary to select the basis best suited to the application. The **as-received** basis represents the weight percentage of each constituent in the sample as received in the laboratory. The sample itself may be coal as fired, as mined, or as prepared for a particular use. The **moisture-free** (dry) basis is a useful basis because performance calculations can be easily corrected for the actual moisture content at the point of use. The **dry, ash-free** basis is frequently used to approximate the rank and source of a coal. For example, the heating value of coal from a given deposit is remarkably constant when calculated on this basis.

The composition of the coal is reported in two different ways: the proximate analysis and the ultimate analysis, both expressed in weight percent. The **proximate analysis** [ASTM D 3172-89 (2002), ASTM International, op. cit.] is the determination by prescribed methods of moisture, volatile matter, fixed carbon, and ash. The moisture in coal consists of inherent moisture, also called equilibrium moisture, and surface moisture. Free moisture is that moisture lost when coal is air-dried under standard low-temperature conditions. The **volatile matter** is the portion of coal which, when the coal is heated in the absence of air under prescribed conditions, is liberated as gases and vapors. Volatile matter does not exist by itself in coal, except for a little absorbed methane, but results from thermal decomposition of the coal substance. **Fixed carbon**, the residue left after the volatile matter is driven off, is calculated by subtracting from 100 the percentages of moisture, volatile matter, and ash of the proximate analysis. In addition to carbon, it may contain several tenths of a percent of hydrogen and oxygen, 0.4 to 1.0 percent nitrogen, and about half of the sulfur that was in the coal. **Ash** is the inorganic residue that remains after the coal has been burned under specified conditions, and it is composed largely of compounds of silicon, aluminum, iron, and calcium, and minor amounts of compounds of magnesium, sodium, potassium, phosphorous, sulfur, and titanium. Ash may vary considerably from the original mineral matter, which is largely kaolinite, illite, montmorillonite, quartz, pyrites, and calcite. The **ultimate analysis** [ASTM D 3176-89 (2002), ASTM International, op. cit.] is the determination by prescribed methods of the ash, carbon, hydrogen, nitrogen, sulfur, and (by difference) oxygen. Other, minor constituent elements are also sometimes determined, most notably chlorine.

The **heating value**, or **calorific value**, expressed as kJ/kg (Btu/lb), is the heat produced at constant volume by the complete combustion of a unit quantity of coal in an oxygen-bomb calorimeter under specified conditions (ASTM D 5865-04, ASTM International, op.cit.). The result includes the latent heat of vaporization of the water in the combustion products and is called the gross heating or **high heating value** (HHV)  $Q_h$ . And  $Q_h$  in Btu/lb ( $\times 2.326 = \text{kJ/kg}$ ) on a dry basis can be approximated by a formula developed by the Institute of Gas Technology:

$$Q_h = 146.58C + 568.78H + 29.4S - 6.58A - 51.53(O + N) \tag{24-4}$$

where *C*, *H*, *S*, *A*, *O*, and *N* are the weight percentages on a dry basis of carbon, hydrogen, sulfur, ash, oxygen, and nitrogen, respectively. The heating value when the water is not condensed is called the **low heating value** (LHV)  $Q_l$  and is obtained from

$$Q_l = Q_h - K \cdot W \tag{24-5}$$

where *W* = weight of water in the combustion products/weight of fuel burned. The factor *K* is the latent heat of vaporization at the partial pressure of the vapor in the gas, which, at 20°C, is 2395 kJ/kg (1030 Btu/lb) of water. Thus,

$$Q_l = Q_h - \%H \cdot 214 \text{ kJ/kg} \tag{24-6}$$

$$Q_l = Q_h - \%H \cdot 92.04 \text{ Btu/lb} \tag{24-7}$$

where %*H* = weight percent hydrogen in the coal and all values are on an as-determined (including moisture) basis.

**Sulfur** Efforts to abate atmospheric pollution have drawn considerable attention to the sulfur content of coal, since the combustion of coal results in the discharge to the atmosphere of sulfur oxides. Sulfur occurs in coal in three major forms: as organic sulfur (20 to 80 percent of the sulfur), which is a part of the coal substance; as pyrite (FeS<sub>2</sub>); and as sulfate (<5 percent of the sulfur in unoxidized coals). Organic sulfur is chemically bound to the coal substance, and severe treatment is necessary to break the chemical bonds to remove the sulfur. There is no existing economical method that will remove organic sulfur. Pyritic sulfur can be partially removed by using standard coal-washing equipment. The degree of pyrite removal depends on the size of the coal and the size and distribution of the pyrite particles.

The sulfur content of U.S. coals varies widely, ranging from a low of 0.2 percent to as much as 7 percent by weight, on a dry basis. The estimated remaining (as of 1997) recoverable U.S. coal reserves of all ranks, by sulfur content and major producing region, are shown in Table 24-2. The values in the table are in units of 10<sup>9</sup> metric tonnes (Pg) as reported in *U.S. Coal Reserves: 1997 Update*, DOE/EIA-0529(97). Extensive data on sulfur and sulfur reduction potential, including washability, in U.S. coals are given in *Sulfur and Ash Reduction Potential and Selected Chemical and Physical Properties of United States Coal* (U.S. Dept. of Energy, DOE/PETC, TR-90/7, 1990; TR-91/1 and TR-91/2, 1991).

**Mercury** Impending regulations limiting the emission of mercury from coal-fired furnaces have created great interest in knowing the concentration of mercury in various coals, determining the fate of mercury during combustion, and developing methods to control mercury emissions to the atmosphere. Most commercially produced U.S. coals have mercury contents of about 0.05 to 0.2 mg/kg, dry basis, although numerous individual coals fall outside that range. Depending on the specific coal properties, furnace conditions, and type and configuration of pollution control devices with which the furnace is equipped, less than 10 percent or more than 90 percent of the coal mercury will be emitted to the atmosphere with the flue gas. The chemical form of the vaporous mercury in the flue gas, whether elemental or ionic, is important, because ionic mercury is easier to capture with available technology than is elemental mercury. The chemical form is apparently influenced by the chlorine content of the coal: coals with higher chlorine contents (0.05 percent and higher) tend to produce mainly ionic mercury in their flue gases, and thus the mercury emissions from these coals are more easily controlled.

**Coal-Ash Characteristics and Composition** When coal is to be burned, used in steel making, or gasified, it is often important to know the ash fusibility, or the temperatures at which formed pyramids of ash attain certain defined stages of fusing in either a mildly reducing or an oxidizing atmosphere; these temperatures are known as the initial deformation, softening, hemispherical, and fluid temperatures. The procedure for determining the fusibility of coal ash is prescribed by ASTM D 1857-04 (ASTM International, op. cit.). The ash fusibility temperatures are most often used as indicators of the tendency of the ash to form sintered or fused masses, which can impede gas flow through a grate and impair heat flow through furnace heat-transfer surfaces, or as indicators of the flowability of ash in slag-tap and cyclone furnaces. However, because ash fusibility is not an infallible index of ash behavior in practice, care is needed in using fusibility data for designing and operating purposes. There is an excellent discussion on this subject in *Steam: Its Generation and Use* (40th ed., Babcock & Wilcox Co., New York, 1992).

**TABLE 24-2 Estimate of Recoverable U.S. Coal Reserves by Sulfur Ranges and Regions (Pg)**

|            | Low sulfur* | Medium sulfur* | High sulfur* | Total |
|------------|-------------|----------------|--------------|-------|
| Appalachia | 10.6        | 18.4           | 21.1         | 50.2  |
| Interior   | 0.7         | 9.1            | 52.6         | 62.4  |
| West       | 79.6        | 49.5           | 8.0          | 137.1 |
| U.S. total | 90.9        | 77.0           | 81.7         | 249.6 |

\*Sulfur content ranges defined in units of kg S/kJ (lb-S/MBtu) as follows: low sulfur, < 0.29 (< 0.60); medium sulfur, 0.29 to 0.80 (0.61 to 1.67); high sulfur, > 0.80 (>1.67).

## 24-6 ENERGY RESOURCES, CONVERSION, AND UTILIZATION

The composition of coal ash varies widely. Calculated as oxides, the composition (percent by weight) varies as follows:

|  |         |
|--|---------|
| SiO <sub>2</sub>                       | 20–60   |
| Al <sub>2</sub> O <sub>3</sub>         | 10–35   |
| Fe <sub>2</sub> O <sub>3</sub>         | 5–35    |
| CaO                                    | 1–20    |
| MgO                                    | 0.3–4   |
| TiO <sub>2</sub>                       | 0.5–2.5 |
| P <sub>2</sub> O <sub>5</sub>          | 0.01–1  |
| Na <sub>2</sub> O and K <sub>2</sub> O | 1–4     |
| SO <sub>3</sub>                        | 0.1–12  |

Knowledge of the composition of coal ash is useful for estimating and predicting the fouling and corrosion of heat-exchange surfaces in pulverized-coal-fired furnaces and in coke making. Multiple correlations for ash composition and ash fusibility are discussed in *Coal Conversion Systems Technical Data Book* (part IA, U.S. Dept. of Energy, 1984). The slag viscosity-temperature relationship provided in that reference for completely melted slag is

$$\text{Log viscosity} = \frac{10^7 M}{(T - 150)^2 + C} \quad (24-8)$$

where viscosity is in poise ( $\times 0.1 = \text{Pa}\cdot\text{s}$ ),  $M = 0.00835(\text{SiO}_2) + 0.00601(\text{Al}_2\text{O}_3) - 0.109$ ,  $C = 0.0415(\text{SiO}_2) + 0.0192(\text{Al}_2\text{O}_3) + 0.0276$  (equivalent  $\text{Fe}_2\text{O}_3$ )  $+ 0.0160(\text{CaO}) - 3.92$ , and  $T = \text{temperature, K}$ .

The oxides in parentheses are the weight percentages of these oxides when  $\text{SiO}_2 + \text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3 + \text{CaO} + \text{MgO}$  are normalized to 100 percent.

**Physical Properties** The *free-swelling index* (FSI) measures the tendency of a coal to swell when burned or gasified in fixed or fluidized beds. Coals with a high FSI (greater than 4) can usually be expected to cause difficulties in such beds. Details of the test are given by the ASTM D 720–91 (2004) (American Society for Testing and Materials, op. cit.) and U.S. Bureau of Mines Report of Investigations 3989.

The *Hardgrove grindability index* (HGI) indicates the ease (or difficulty) of grinding coal and is complexly related to physical properties such as hardness, fracture, and tensile strength. The Hardgrove machine is usually employed (ASTM D 409-02, American Society for Testing and Materials, op. cit.). It determines the relative grindability or ease of pulverizing coal in comparison with a standard coal, chosen as 100 grindability. The FSI and HGI of some U.S. coals are given in Bureau of Mines Information Circular 8025 for FSI and HGI data for 2812 and 2339 samples, respectively.

The *bulk density* of broken coal varies according to the specific gravity, size distribution, and moisture content of the coal and the amount of settling when the coal is piled. Following are some useful approximations of the bulk density of various ranks of coal.

|            | kg/m <sup>3</sup> | lb/ft <sup>3</sup> |
|------------|-------------------|--------------------|
| Anthracite | 800–930           | 50–58              |
| Bituminous | 670–910           | 42–57              |
| Lignite    | 640–860           | 40–54              |

*Size stability* refers to the ability of coal to withstand breakage during handling and shipping. It is determined by dropping a sample of coal onto a steel plate in a specified manner and comparing the size distribution before and after the test, as in ASTM D 440-86 (2002) (ASTM International, op. cit.). A complementary property, *friability*, is the tendency of coal to break during repeated handling, and it is determined by the standard tumbler test, as in ASTM D 441-86 (2002) (ASTM International, op. cit.).

Spier's *Technical Data on Fuels* gives the *specific heat* of dry, ash-free coal as follows.

|            | kJ/(kg·K) | Btu/(lb·°F) |
|------------|-----------|-------------|
| Anthracite | 0.92–0.96 | 0.22–0.23   |
| Bituminous | 1.0–1.1   | 0.24–0.25   |

The relationships between specific heat and water content and between specific heat and ash content are linear. Given the specific heat on a dry, ash-free basis, it can be corrected to an as-received

basis. The specific heat and enthalpy of coal to 1366 K (2000°F) are given in *Coal Conversion Systems Technical Data Book* (part IA, U.S. Dept. of Energy, 1984).

The *mean specific heat* of coal ash and slag, which is used for calculating heat balances on furnaces, gasifiers, and other coal-consuming systems, follows.

| Temperature range |         | Mean specific heat |             |
|-------------------|---------|--------------------|-------------|
| K                 | °F      | kJ/(kg·K)          | Btu/(lb·°F) |
| 273–311           | 32–100  | 0.89               | 0.21        |
| 273–1090          | 32–1500 | 0.94               | 0.22        |
| 273–1310          | 32–1900 | 0.97               | 0.23        |
| 273–1370          | 32–2000 | 0.98               | 0.24        |
| 273–1640          | 32–2500 | 1.1                | 0.27        |

**Coke** Coke is the solid, cellular, infusible material remaining after the carbonization of coal, pitch, petroleum residues, and certain other carbonaceous materials. The varieties of coke generally are identified by prefixing a word to indicate the source, if other than coal, (e.g., *petroleum coke*), the process by which a coke is manufactured (e.g., vertical slot oven coke), or the end use (e.g., blast furnace coke). The carbonization of coal into coke involves a complex set of physical and chemical changes. Some of the physical changes are softening, devolatilization, swelling, and resolidification. Some of the accompanying chemical changes are cracking, depolymerization, polymerization, and condensation. More detailed theoretical information is given in the general references listed in the beginning of the section on coal.

**High-Temperature Coke** (1173 to 1423 K or 1652 to 2102°F.) Essentially all coal-derived coke produced in the United States is high-temperature coke for metallurgical applications; its production comprises nearly 5 percent of the total bituminous coal consumed in the United States. About 90 percent of this type of coke is made in slot-type by-product recovery ovens, and the rest is made in heat recovery ovens. Blast furnaces use about 90 percent of the production, the rest going mainly to foundries and gas plants. The ranges of chemical and physical properties of metallurgical coke used in the United States are given in Table 24-3. Blast furnaces use about 90 percent of the production, the rest going mainly to foundries and gas plants.

The typical by-product yields per U.S. ton (909 kg) of dry coal from high-temperature carbonization in ovens with inner-wall temperatures from 1273 to 1423 K (1832 to 2102°F) are: coke, 653 kg (1437 lb); gas, 154 kg (11,200 ft<sup>3</sup>); tar, 44 kg (10 gal); water, 38 kg (10 gal); light oil, 11 kg (3.3 gal); and ammonia, 2.2 kg (4.8 lb).

**Foundry Coke** This coke must meet specifications not required of blast furnace coke. The volatile matter should not exceed 1.0 percent, the sulfur should not exceed 0.7 percent, the ash should not exceed 8.0 percent, and the size should exceed 100 mm (4 in).

**Low- and Medium-Temperature Coke** (773 to 1023 K or 932 to 1382°F.) Cokes of this type are no longer produced in the United States to a significant extent. However, there is some interest in low-temperature carbonization as a source of both hydrocarbon liquids and gases to supplement petroleum and natural-gas resources.

**Pitch Coke and Petroleum Coke** Pitch coke is made from coal-tar pitch, and petroleum coke is made from petroleum residues from petroleum refining. Pitch coke has about 1.0 percent volatile matter, 1.0 percent ash, and less than 0.5 percent sulfur on the as-received basis. There are two kinds of petroleum coke: delayed coke and fluid coke. Delayed coke is produced by heating a gas oil or heavier feedstock to

**TABLE 24-3 Chemical and Physical Properties of Metallurgical Cokes Used in the United States**

| Property                                | Range of values     |
|---|---------------------|
| Volatile matter                         | 0.5–1.0%, dry basis |
| Ash content                             | 8–12%, dry basis    |
| Sulfur content                          | 0.6–1.0%, dry basis |
| Stability factor                        | 55–65               |
| Hardness factor                         | 60–68               |
| Strength after reaction                 | 55–65               |
| Apparent specific gravity (water = 1.0) | 0.8–0.99            |

TABLE 24-4 Waste Fuel Analysis

| Type of waste             | Heating value, Btu/lb | Percentage composition by weight |          |       |        |                 | Density, lb/ft <sup>3</sup> |
|---------------------------|-----------------------|----------------------------------|----------|-------|--------|-----------------|-----------------------------|
|                           |                       | Volatiles                        | Moisture | Ash   | Sulfur | Dry combustible |                             |
| Paper                     | 7,572                 | 84.6                             | 10.2     | 6.0   | 0.20   |                 |                             |
| Wood                      | 8,613                 | 84.9                             | 20.0     | 1.0   | 0.05   |                 |                             |

To convert British thermal units per pound to joules per kilogram, multiply by 2326; to convert pounds per cubic foot to kilograms per cubic meter, multiply by 16.02.

755 to 811 K (900 to 1000°F) and spraying it into a large vertical cylinder where cracking and polymerization reactions occur. Fluid coke is made in a fluidized-bed reactor where preheated feed is sprayed onto a fluidized bed of coke particles. Coke product is continuously withdrawn by size classifiers in the solids loop of the reactor system. Petroleum coke contains many of the impurities from its feedstock; thus, the sulfur content is usually high, and appreciable quantities of vanadium may be present. Ranges of composition and properties are as follows:

| Composition and properties      | Delayed coke | Fluid coke |
|---------------------------------|--------------|------------|
| Volatile matter, wt %           | 8–18         | 3.7–7.0    |
| Ash, wt %                       | 0.05–1.6     | 0.1–2.8    |
| Sulfur, wt %                    | —            | 1.5–10.0   |
| Grindability index              | 40–60        | 20–30      |
| True density, g/cm <sup>3</sup> | 1.28–1.42    | 1.5–1.6    |

Most petroleum coke is used for fuel, but some premium delayed coke known as “needle coke” is used to make anodes for the aluminum industry. That coke is first calcined to less than 0.5 percent volatiles at 1300 to 1400°C before it is used to make anodes.

### Other Solid Fuels

**Coal Char** Coal char is, generically, the nonagglomerated, nonfusible residue from the thermal treatment of coal; however, it is more specifically the solid residue from low- or medium-temperature carbonization processes. Char is used as a fuel or a carbon source. Chars have compositions intermediate between those of coal and coke: the volatile matter, sulfur content, and heating values of the chars are lower, and the ash content is higher, than those of the original coal.

**Peat** Peat is partially decomposed plant matter that has accumulated in a water-saturated environment. It is the precursor of coal but is not classified as coal. Peat is used extensively as a fuel primarily in Ireland and the former Soviet Union, but in the United States, its main use is in horticulture and agriculture. Although analyses of peat vary widely, a typical high-grade peat has 90 percent water, 3 percent fixed carbon, 5 percent volatile matter, 1.5 percent ash, and 0.10 percent sulfur. The moisture-free heating value is approximately 20.9 MJ/kg (9000 Btu/lb).

**Wood** Typical higher heating values are 20 MJ/kg (8600 Btu/lb) for oven-dried hardwood and 20.9 MJ/kg for oven-dried softwood. These values are accurate enough for most engineering purposes. U.S. Department of Agriculture Handbook 72 (revised 1974) gives the specific gravity of the important softwoods and hardwoods, useful if heating value on a volume basis is needed.

**Charcoal** Charcoal is the residue from the destructive distillation of wood. It absorbs moisture readily, often containing as much as 10 to 15 percent water. In addition, it usually contains about 2 to 3 percent ash and 0.5 to 1.0 percent hydrogen. The heating value of charcoal is about 27.9 to 30.2 MJ/kg (12,000 to 13,000 Btu/lb).

**Solid Wastes and Biomass** The generation of large quantities of solid wastes is a significant feature of affluent societies. In the United

States in 2001 the rate was about 2 kg (4.4 lb) per capita per day, or nearly 208 Tg (229 M short tons) per year. Table 24-4 shows that the composition of miscellaneous refuse is fairly uniform, but size and moisture variations cause major difficulties in efficient, economical disposal. The fuel value of municipal solid wastes is usually sufficient to enable self-supporting combustion, leaving only the incombustible residue and reducing by 90 percent the volume of waste consigned to landfill. The heat released by the combustion of waste can be recovered and utilized, although this is not always economically feasible.

Wood, wood scraps, bark, and wood product plant waste streams are major elements of biomass, industrial, and municipal solid waste fuels. In 1991, about 1.7 EJ ( $1.6 \times 10^{15}$  Btu [quads]) of energy were obtained from wood and wood wastes, representing about 60 percent of the total biomass-derived energy in the United States. *Bagasse* is the solid residue remaining after sugarcane has been crushed by pressure rolls. It usually contains from 40 to 50 percent water. The dry bagasse has a heating value of 18.6 to 20.9 MJ/kg (8000 to 9000 Btu/lb). Tire-derived fuel (TDF), which is produced by shredding and processing waste tires and which has a heating value of 30.2 to 37.2 MJ/kg (13,000 to 16,000 Btu/lb), is an important fuel for use in cement kilns and as a supplement to coal in steam raising.

### LIQUID FUELS

**Liquid Petroleum Fuels** The discussion here focuses on burner fuels rather than transportation fuels. There is overlap, particularly for fuels in the distillate or “gas oil” range. Other factors such as the Tier II gasoline specifications, the ultralow-sulfur diesel specifications, and the gradual reduction in crude quality impact refining and blending practices for burner fuels. The principal liquid fuels are made by fractional distillation of crude petroleum (a mixture of hydrocarbons and hydrocarbon derivatives ranging from methane to heavy bitumen). As many as one-quarter to one-half of the molecules in crude may contain sulfur atoms, and some contain nitrogen, oxygen, vanadium, nickel, or arsenic. Desulfurization, hydrogenation, cracking (to lower molecular weight), and other refining processes may be performed on selected fractions before they are blended and marketed as fuels. Viscosity, gravity, and boiling ranges are given in Table 24-5.

**Specifications** The American Society for Testing and Materials has developed specifications (*Annual Book of ASTM Standards*, Conshohocken, Pa., updated annually) that are widely used to classify fuels. Table 24-5 shows fuels covered by ASTM D 396, Standard Specification for Fuel Oils. D 396 omits kerosenes (low-sulfur, clean-burning No. 1 fuels for lamps and freestanding flueless domestic heaters), which are covered separately by ASTM D 3699.

In drawing contracts and making acceptance tests, refer to the pertinent ASTM standards. *ASTM Standards* contain specifications (classifications) and test methods for burner fuels (D 396), motor and aviation gasolines (D 4814-03 and D 910-03), diesel fuels (D 975-03), and aviation and gas-turbine fuels (D 1655-03 and D 2880-03).

Adapted, with permission, from D396-06, Standard Specification for Fuel Oils; copyright ASTM International, 100 Barr Harbor Drive, West Conshohocken, PA 19428.

<sup>a</sup> It is the intent of these classifications that failure to meet any requirement of a given grade does not automatically place an oil in the next lower grade unless in fact it meets all requirements of the lower grade. However, to meet special operating conditions, modifications of individual limiting requirements may be agreed upon among the purchaser, seller, and manufacturer.

<sup>b</sup> The test methods indicated are the approved referee methods. Other acceptable methods are indicated in Sections 2 and 5.1 of ASTM D 396.

<sup>c</sup> Under U.S. regulations, Grades No. 1, No. 1 Low Sulfur, No. 2, No. 2 Low Sulfur, and No. 4 (Light) are required by 40 CFR Part 80 to contain a sufficient amount of the dye Solvent Red 164 so its presence is visually apparent. At or beyond terminal storage tanks, they are required by 26 CFR Part 48 to contain the dye Solvent Red 164 at a concentration spectrally equivalent to 3.9 lb per thousand barrels of the solid dye standard Solvent Red 26.

<sup>d</sup> The amount of water by distillation by Test Method D 95 plus the sediment by extraction by Test method D 473 shall not exceed the value shown in the table. For Grade No. 6 fuel oil, the amount of sediment by extraction shall not exceed 0.50 mass percent, and a deduction in quantity shall be made for all water and sediment in excess of 1.0 mass percent.

<sup>e</sup> Where low sulfur fuel oil is required, fuel oil falling in the viscosity range of a lower numbered grade down to and including No. 4 can be supplied by agreement between the purchaser and supplier. The viscosity range of the initial shipment shall be identified, and advance notice shall be required when changing from one viscosity range to another. This notice shall be in sufficient time to permit the user to make the necessary adjustments.

<sup>f</sup> Other sulfur limits may apply in selected areas in the United States and in other countries.

<sup>g</sup> This limit ensures a minimum heating value and also prevents misrepresentation and misapplication of this product as Grade No. 2.

<sup>h</sup> Lower or higher pour points can be specified whenever required by conditions of storage or use. When a pour point less than -18°C is specified, the minimum viscosity at 40°C for Grade No. 2 shall be 1.7 mm<sup>2</sup>/s and the minimum 90% recovered temperature shall be waived.

<sup>i</sup> Where low sulfur fuel oil is required, Grade No. 6 fuel oil will be classified as Low Pour (+15°C max) or High Pour (no max). Low Pour fuel oil should be used unless tanks and lines are heated.

ASTM D 4057-95 contains procedures for sampling bulk oil in tanks, barges, etc.

Fuel specifications from different sources may differ in test limits on sulfur, density, etc., but the same general categories are recognized worldwide: kerosene-type vaporizing fuel, distillate (or gas oil) for atomizing burners, and more viscous blends and residuals for commerce and heavy industry.

Foreign specifications are generally available from the American National Standards Institute, New York; United States federal specifications, at Naval Publications and Forms, Philadelphia. The International Association for Stability, Handling and Use of Liquid Fuels maintains a web site, [www.iash.net](http://www.iash.net), with extensive references to fuel standards.

Equipment manufacturers and large-volume users often write fuel specifications to suit particular equipment, operating conditions, and economics. Nonstandard test procedures and restrictive test limits should be avoided; they reduce the availability of fuel and increase its cost.

*Bunker-fuel* specifications for merchant vessels were described by ASTM D 2069, Standard Specification for Marine Fuels, which was withdrawn in 2003. Specifications under ASTM D-396 or foreign specifications may be substituted as appropriate.

**Chemical and Physical Properties** Petroleum fuels contain paraffins, isoparaffins, naphthenes, and aromatics, plus organic sulfur, oxygen, and nitrogen compounds that were not removed by refining. Olefins are absent or negligible except when created by severe refining. Vacuum-tower distillate with a final boiling point equivalent to 730 to 840 K (850 to 1050°F) at atmospheric pressure may contain from 0.1 to

0.5 ppm vanadium and nickel, but these metal-bearing compounds do not distill into No. 1 and 2 fuel oils.

Black, viscous residuum directly from the still at 410 K (390°F) or higher serves as fuel in nearby furnaces or may be cooled and blended to make commercial fuels. Diluted with 5 to 20 percent distillate, the blend is No. 6 fuel oil. With 20 to 50 percent distillate, it becomes No. 4 and No. 5 fuel oils for commercial use, as in schools and apartment houses. Distillate-residual blends also serve as diesel fuel in large stationary and marine engines. However, distillates with inadequate solvent power will precipitate asphaltenes and other high-molecular-weight colloids from *visbroken* (severely heated) residuals. A blotter test, ASTM D 4740-02, will detect sludge in pilot blends. Tests employing centrifuges, filtration (D 4870-99), and microscopic examination have also been used.

No. 6 fuel oil contains from 10 to 500 ppm vanadium and nickel in complex organic molecules, principally porphyrins. These cannot be removed economically, except incidentally during severe hydrodesulfurization (Amero, Silver, and Yanik, *Hydrodesulfurized Residual Oils as Gas Turbine Fuels*, ASME Pap. 75-WA/GT-8). Salt, sand, rust, and dirt may also be present, giving No. 6 a typical ash content of 0.01 to 0.5 percent by weight.

*Ultimate analyses* of some typical fuels are shown in Table 24-6.

The hydrogen content of petroleum fuels can be calculated from density with the following formula, with an accuracy of about 1 percent for petroleum liquids that contain no sulfur, water, or ash:

$$H = 26 - 15s \quad (24-9)$$

**TABLE 24-6 Typical Ultimate Analyses of Petroleum Fuels**

| Composition, % | No. 1 fuel oil<br>(41.5° API) | No. 2 fuel oil<br>(33° API) | No. 4 fuel oil<br>(23.2° API) | Low sulfur,<br>No. 6 F.O.<br>(12.6° API) | High sulfur,<br>No. 6<br>(15.5° API) |
|----------------|-------------------------------|-----------------------------|-------------------------------|--|--------------------------------------|

| Nitrogen       | 0.003                         | 0.006                       | 0.24                          | 0.28                                     | 0.18                                 |
| Sulfur         | 0.09                          | 0.22                        | 1.35                          | 0.84                                     | 3.97                                 |
| Ash            | <0.01                         | <0.01                       | 0.02                          | 0.04                                     | 0.02                                 |
| C/H Ratio      | 6.35                          | 6.93                        | 7.42                          | 8.31                                     | 7.62                                 |

NOTE: The C/H ratio is a weight ratio.

where  $H$  = percent hydrogen and  $s$  = relative density at 15°C (with respect to water), also referred to as specific gravity.

Relative density is usually determined at ambient temperature with specialized hydrometers. In the United States these hydrometers commonly are graduated in an arbitrary scale termed *degrees API*. This scale relates inversely to relative density  $s$  (at 60°F) as follows (see also the abscissa scale of Fig. 24-1):

$$\text{Degrees API} = \frac{141.5}{s} - 131.5 \quad (24-10)$$

For practical engineering purposes, relative density at 15°C (288 K), widely used in countries outside the United States, is considered equivalent to specific gravity at 60°F (288.6 K). With the adoption of

SI units, the American Petroleum Institute favors absolute density at 288 K instead of degrees API.

The hydrogen content, heat of combustion, specific heat, and thermal conductivity data herein were abstracted from Bureau of Standards Miscellaneous Publication 97, *Thermal Properties of Petroleum Products*. These data are widely used, although other correlations have appeared, notably that by Linden and Othmer (*Chem. Eng.* 54[4, 5], April and May, 1947).

Heat of combustion can be estimated within 1 percent from the relative density of the fuel by using Fig. 24-1. Corrections for water and sediment must be applied for residual fuels, but they are insignificant for clean distillates.

Pour point ranges from 213 K (−80°F) for some kerosene-type jet fuels to 319 K (115°F) for waxy No. 6 fuel oils. Cloud point (which is not measured on opaque fuels) is typically 3 to 8 K higher than pour point unless the pour has been depressed by additives. Typical petroleum fuels are practically newtonian liquids between the cloud point and the boiling point and at pressures below 6.9 MPa (1000 psia).

Fuel systems for No. 1 (kerosene) and No. 2 fuel oil (diesel, home heating oil) are not heated. Systems for No. 6 fuel oil are usually designed to preheat the fuel to 300 to 320 K (90 to 120°F) to reduce viscosity for handling and to 350 to 370 K (165 to 200°F) to reduce viscosity further for proper atomization. No. 5 fuel oil may also be heated, but preheating is usually not required for No. 4. (See Table 24-5.) Steam or electric heating is employed as dictated by economics, climatic conditions, length of storage time, and frequency of use. Pressure relief arrangements are recommended on sections of heated pipelines when fuel could be inadvertently trapped between valves.

The kinematic viscosity of a typical No. 6 fuel oil declines from 5000 mm<sup>2</sup>/s (0.054 ft<sup>2</sup>/s) at 298 K (77°F) to about 700 mm<sup>2</sup>/s (0.0075 ft<sup>2</sup>/s) and 50 mm<sup>2</sup>/s (0.000538 ft<sup>2</sup>/s) on heating to 323 K (122°F) and 373 K (212°F), respectively. Viscosity of 1000 mm<sup>2</sup>/s or less is required for manageable pumping. Proper boiler atomization requires a viscosity between 15 and 65 mm<sup>2</sup>/s.

Thermal expansion of petroleum fuels can be estimated as volume change per unit volume per degree. ASTM-IP Petroleum Measurement Tables (ASTM D 1250 IP 200) are used for volume corrections in commercial transactions.

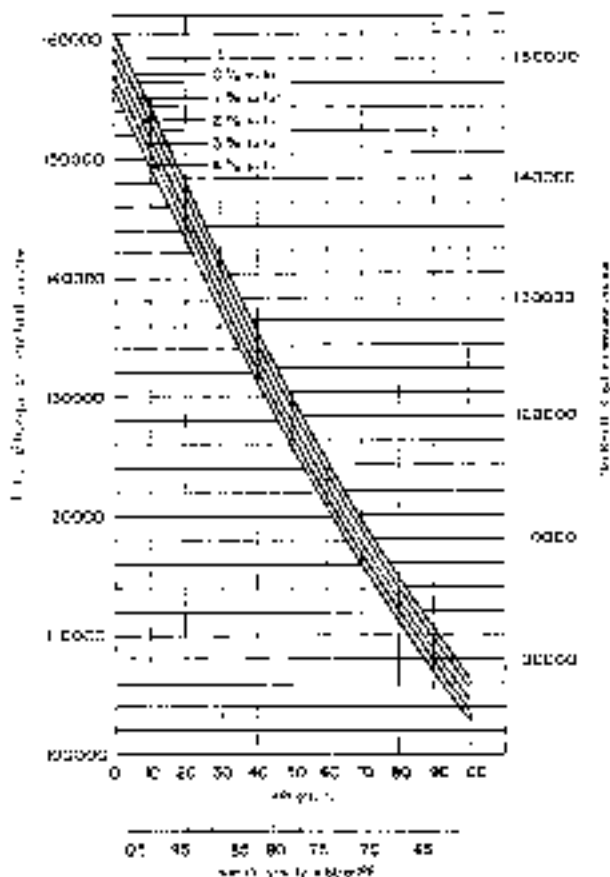

Heat capacity (specific heat) of petroleum liquids between 0 and 205°C (32 and 400°F), having a relative density of 0.75 to 0.96 at 15°C (60°F), can be calculated within 2 to 4 percent of the experimental values from the following equations:

$$c = \frac{1.685 + (0.039 \times ^\circ\text{C})}{\sqrt{s}} \quad (24-11)$$

$$c' = \frac{0.388 + (0.00045 \times ^\circ\text{F})}{\sqrt{s}} \quad (24-12)$$

where  $c$  is heat capacity, kJ/(kg·°C) or kJ/(kg·K), and  $c'$  is heat capacity, Btu/(lb·°F). Heat capacity varies with temperature, and the arithmetic average of the values at the initial and final temperatures can be used for calculations relating to the heating or cooling of oil.

The thermal conductivity of liquid petroleum products is given in Fig. 24-2. Thermal conductivities for asphalt and paraffin wax in their solid states are 0.17 and 0.23 W/(m·K), respectively, for temperatures above 273 K (32°F) (1.2 and 1.6 Btu/[h·ft<sup>2</sup>][°F/in]).

**FIG. 24-1** Heat of combustion of petroleum fuels. To convert Btu/U.S. gal to kJ/m<sup>3</sup>, multiply by 278.7.

FIG. 24-2 Thermal conductivity of petroleum liquids. The solid lines refer to density expressed as degrees API; the broken lines refer to relative density at 288 K (15°C). ( $K = [^{\circ}F + 459.7]/1.8$ )

**Commercial Considerations** Fuels are sold in gallons and in multiples of the 42-gal barrel (0.159 m<sup>3</sup>) in the United States, while a weight basis is used in other parts of the world. Transactions exceeding about 20 to 40 m<sup>3</sup> (5000 to 10,000 U.S. gal) usually involve volume corrections to 288 K (60°F) for accounting purposes. Fuel passes through an air eliminator and mechanical meter when loaded into or dispensed from trucks. Larger transfers such as pipeline, barge, or tanker movements are measured by fuel depth and strapping tables (calibration tables) in tanks and vessels, but positive-displacement meters that are proved (calibrated) frequently are gaining acceptance. After an appropriate settling period, water in the tank bottom is measured with a plumb bob or stick smeared with water-detecting paste.

Receipts of tank-car quantities or larger are usually checked for gravity, appearance, and flash point to confirm product identification and absence of contamination.

**Safety Considerations** Design and location of storage tanks, vents, piping, and connections are specified by state fire marshals, underwriters' codes, and local ordinances. In NFPA 30, *Flammable and Combustible Liquids Code, 2003* (published by the National Fire Protection Association, Quincy, Ma.), liquid petroleum fuels are placed in Class I through Class III B based on their flash point, boiling point, and vapor pressure.

NFPA 30 details the design features and safe placement of handling equipment for flammable and combustible liquids.

Crude oils with flash points below 311 K (100°F) have been used in place of No. 6 fuel oil. Different pumps may be required because of low fuel viscosity.

### Nonpetroleum Liquid Fuels

**Tar Sands** Canadian tar sands either are strip-mined and extracted with hot water or employ steam-assisted gravity drainage (SAGD) for in situ recovery of heavy oil (bitumen). The bitumen is processed into naphtha, kerosine, and gasoline fractions (which are hydrotreated), in addition to gas (which is recovered). Current production of syncrude from Canadian tar sands is about 113,000 T/d (790,000 B/d) with expected increases to about 190,000 T/d (1.7 MB/d) by 2010.

**Oil Shale** Oil shale is nonporous rock containing organic kerogen. Raw shale oil is extracted from mined rock by pyrolysis in a surface retort, or in situ by partial combustion after breaking up the rock with explosives. Pyrolysis cracks the kerogen, yielding raw shale oil high in nitrogen, oxygen, and sulfur. **Shale oil** has been hydrotreated

and refined in demonstration tests into relatively conventional fuels. Refining in petroleum facilities is possible with significant pretreatment or by incorporating upgrading units into the refinery.

**Coal-Derived Fuels** Liquid fuels derived from coal range from highly aromatic coal tars to liquids resembling petroleum. Raw liquids from different hydrogenation processes show variations that reflect the degree of hydrogenation achieved. Also, the raw liquids can be further hydrogenated to refined products. Properties and cost depend on the degree of hydrogenation and the boiling range of the fraction selected. A proper balance between fuel upgrading and equipment modification is essential for the most economical use of coal liquids in boilers, industrial furnaces, diesels, and stationary gas turbines.

**Coal-tar fuels** are high-boiling fractions of crude tar from pyrolysis in coke ovens and coal retorts. Grades range from free-flowing liquids to pulverizable pitch. Low in sulfur and ash, they contain hydrocarbons, phenols, and heterocyclic nitrogen and oxygen compounds. Being more aromatic than petroleum fuels, they burn with a more luminous flame. From 288 to 477 K (60 to 400°F) properties include:

|                      |   |
|----------------------|---|
| Heat capacity        | 1.47–1.67 kJ/(kg·K) (0.35–0.40 Btu/[lb·°F])   |
| Thermal conductivity | 0.14–0.15 W/(m·K) (0.080–0.085 Btu/[h·ft·°F]) |
| Heat of vaporization | 349 kJ/kg (150 Btu/lb)                        |
| Heat of fusion       | Nil   |

Table 24-7 shows representative data for liquid fuels from tar sands, oil shale, and coal.

### GASEOUS FUELS

**RESERVE AND PRODUCTION INFORMATION:** DOE/EIA-0216(2003), November 2004; U.S. Crude Oil, Natural Gas, and Natural Gas Liquids Reserves: 2003 Annual Report, Table 2, Table 8, Table 12; *Annual Energy Review 2003*, DOE/EIA-0364, September 2004; *Natural Gas Annual 2003*, DOE/EIA-0131(03), December 2004, Table 9.

**Natural Gas** Natural gas is a combustible gas that occurs in porous rock of the earth's crust and is often found with accumulations of crude oil or coal. Natural gas termed *dry* has less than 0.013 dm<sup>3</sup>/m<sup>3</sup> (0.1 gal/1000 ft<sup>3</sup>) of gasoline. Above this amount, it is termed *wet*.

Proven reserves of conventionally reservoired natural gas in the United States total about 5.35 Tm<sup>3</sup> (189 Tft<sup>3</sup>). An additional 0.53 Tm<sup>3</sup> (18.7 Tft<sup>3</sup>) of proven reserves are in coal bed methane deposits. Production in 2003 was about 0.54 Tm<sup>3</sup> (19.1 Tft<sup>3</sup>), over 75 percent

<sup>a</sup>CTF 50 and 400 indicate approximate preheat temperature, °F, for atomization of fuel in burners (terminology used in British Standard B.S. 1469).

<sup>b</sup>Properties depend on distillation range, as shown, and to a lesser extent on coal source.

<sup>c</sup>Using recycle-solvent process.

<sup>d</sup>Tar sands, although a form of petroleum, are included in this table for comparison.

<sup>e</sup>Inorganic mineral constituents of coal tar fuel:

5 to 50 ppm: Ca, Fe, Pb, Zn (Na, in tar treated with soda ash)

0.05 to 5 ppm: Al, Bi, Cu, Mg, Mn, K, Si, Na, Sn

Less than 0.05 ppm: As, B, Cr, Ge, Ti, V, Mo

Not detected: Sb, Ba, Be, Cd, Co, Ni, Sr, W, Zr

<sup>f</sup>Inherent ash is “trace” or “<0.1%,” although entrainment in distillation has given values as high as 0.03 to 0.1%.

from nonassociated gas wells. Conventional proven reserves have declined about 0.03 Tm<sup>3</sup> (0.9 Tft<sup>3</sup>) per year from 1977 through 2003. Net gas imports in 2003 were 0.09 Tm<sup>3</sup> (3.3 Tft<sup>3</sup>), about 15 percent of consumption. Imports as LNG were 0.4 Tft<sup>3</sup>, about 2 percent of gas consumption.

Natural gas consists of hydrocarbons with a very low boiling point.

Methane is the main constituent, with a boiling point of 119 K (–245°F). Ethane, with a boiling point of 184 K (–128°F) may be present in amounts up to 10 percent; propane, with a boiling point of 231 K (–44°F), up to 3 percent. Butane, pentane, hexane, heptane, and octane may also be present. Physical properties of these hydrocarbons are given in Sec. 2.

Although there is no single composition that may be called “typical” natural gas, Table 24-8 shows the range of compositions in large cities in the United States.

**TABLE 24-8 Analysis of Natural Gas\***

|  | Range <sup>†</sup> |             |
|--|--------------------|-------------|
|  | Low                | High        |

\*Adapted from *Gas Engineers Handbook*, American Gas Association, Industrial Press, New York, 1965.

<sup>†</sup>Ranges are the high and low values of annual averages reported by 13 utilities (1954 data).

Commodity natural gas is substantially free of sulfur compounds; the terms *sweet* and *sour* are used to denote the absence or presence of H<sub>2</sub>S. Some wells, however, deliver gas containing levels of hydrogen sulfide and other sulfur compounds (e.g., thiophenes, mercaptans, and organic sulfides) that must be removed before transfer to commercial pipelines. Pipeline-company contracts typically specify maximum allowable limits of impurities; H<sub>2</sub>S and total sulfur compounds seldom exceed 0.023 and 0.46 g/m<sup>3</sup> (1.0 and 20.0 gr/100 std ft<sup>3</sup>), respectively. The majority of pipeline companies responding to a 1994 survey limited H<sub>2</sub>S to less than 0.007 g/m<sup>3</sup> (0.3 gr/100 std ft<sup>3</sup>), but a slightly smaller number continued specifying 0.023 g/m<sup>3</sup>, in accord with an American Gas Association 1971 recommendation.

**Supercompressibility of Natural Gas** All gases deviate from the simple gas laws to a varying extent. This deviation is called *supercompressibility* and must be taken into account in gas measurement, particularly at high line pressure. For example, since natural gas is more compressible under high pressure at ordinary temperatures than is called for by Boyle’s law, gas purchased at an elevated pressure gives a greater volume when the pressure is reduced than it would if the gas were ideal.

The supercompressibility factor may be expressed as

$$Z = (RT/PV)^{1/2} \tag{24-13}$$

where  $Z$  = supercompressibility factor;  $R$  = universal gas constant, 8.314 kPa·m<sup>3</sup>/(kmol·K);  $T$  = gas temperature, K;  $P$  = gas pressure, kPa;  $V$  = molar gas volume, m<sup>3</sup>/kmol.

For determining supercompressibility factors of natural gas mixtures, see *Manual for the Determination of Supercompressibility Factors for Natural Gas*, American Gas Association, New York, 1963; and A.G.A Gas Measurement Committee Report No. 3, 1969.

**Liquefied Natural Gas** The advantages of storing and shipping natural gas in liquefied form (LNG) derive from the fact that 0.035 m<sup>3</sup> (1 ft<sup>3</sup>) of liquid methane at 111 K (–260°F) equals about 18 m<sup>3</sup> (630 ft<sup>3</sup>) of gaseous methane. One cubic meter (264 U.S. gal) weighs 412 kg (910 lb) at 109 K (–263°F). The heating value is about 24 GJ/m<sup>3</sup> (86,000 Btu/U.S. gal). The heat of vaporization of LNG at 0.1 MPa is 232 MJ/m<sup>3</sup> of liquid. On a product gas basis, the heat required is about 0.3 kJ/m<sup>3</sup> (10 Btu/std ft<sup>3</sup>) of gas produced.

LNG is actively traded in international commerce. In 2003 LNG was about 13 percent of gas imports to the United States but only 2 percent of gas consumption. The Energy Information Administration (EIA) projects (Annual Energy Outlook 2004) that gas imports will grow to 5.5 Tft<sup>3</sup> in 2010 and to 7.2 Tft<sup>3</sup> in 2025, with nearly all the increased volume being LNG.

Specialized ships are used to transport LNG. Receiving terminals have storage tankage and reevaporization facilities. Several new terminals have been proposed, but none has advanced to construction at this writing.

**Liquefied Petroleum Gas** The term *liquefied petroleum gas* (LPG) is applied to certain specific hydrocarbons which can be liquefied under moderate pressure at normal temperatures but are gaseous under normal atmospheric conditions. The chief constituents of LPG are propane, propylene, butane, butylene, and isobutane. LPG produced in the separation of heavier hydrocarbons from natural gas is mainly of the paraffinic (saturated) series. LPG derived from oil-refinery gas may contain varying low amounts of olefinic (unsaturated) hydrocarbons.

LPG is widely used for domestic service, supplied either in tanks or by pipelines. It is also used to augment natural gas deliveries on peak days and by some industries as a standby fuel.

### Other Gaseous Fuels

**Hydrogen** Hydrogen is used extensively in the production of ammonia and chemicals, in the refining of petroleum, in the hydrogenation of fats and oils, and as an oven reducing atmosphere. It is also used as a fuel in industrial cutting and welding operations. There are no resources of uncombined hydrogen as there are of the other fuels. It is made industrially by the steam reforming of natural gas; as the by-product of industrial operations such as the thermal cracking of hydrocarbons; and, to a small extent, by the electrolysis of water.

Hydrogen is seen as the ultimate nonpolluting form of energy; when electrochemically combined with oxygen in fuel cells, only water, heat, and electricity are produced. Means for transforming the world's fossil energy economy into a hydrogen economy are being considered as a long-term option. Hydrogen can be stored in gaseous, liquid, or solid forms; however, currently available technologies are not suited to meet mass energy market needs. Technologies for economically producing, storing, and utilizing hydrogen are being researched in the United States, Europe, and Japan.

**Acetylene** Acetylene is used primarily in operations requiring high flame temperature, such as welding and metal cutting. To transport acetylene, it is dissolved in acetone under pressure and drawn into small containers filled with porous material.

**Miscellaneous Fuels** A variety of gases have very minor market shares. These include reformed gas, oil gases, producer gas, blue water gas, carbureted water gas, coal gas, and blast-furnace gas. The heating values of these gases range from 3.4 to 41 MJ/m<sup>3</sup> (90 to 1100 Btu/ft<sup>3</sup>). They are produced by pyrolysis, the water gas reaction, or as by-products of pig-iron production.

Hydrogen sulfide in manufactured gases may range from approximately 2.30 g/m<sup>3</sup> (100 gr/100 ft<sup>3</sup>) in blue and carbureted water gas to several hundred grains in coal- and coke-oven gases. Another important sulfur impurity is carbon disulfide, which may be present in amounts varying from 0.007 to 0.07 percent by volume. Smaller amounts of carbon oxysulfide, mercaptans, and thiophene may be found. However, most of the impurities are removed during the purification process and either do not exist in the finished product or are present in only trace amounts.

### FUEL AND ENERGY COSTS

Fuel costs vary widely both geographically and temporally. Oil and gas markets have been highly volatile in recent years while steam coal markets have not. Much combustion equipment is designed for a specific fuel, limiting the potential for fuel switching to take advantage of price trends. The costs given in Table 24-9 are U.S. averages not necessarily applicable to a specific location; they do provide fuel cost trends.

**TABLE 24-9 Time-Price Relationships for Fossil Fuels**

| Year | Bituminous coal, \$/Mg (\$/U.S. ton) | Wellhead natural gas, \$/1000 m <sup>3</sup> (\$/1000 scf) | Crude oil, domestic first purchase price, \$/m <sup>3</sup> (\$/bbl) |
|------|--------------------------------------|--|--|
| 1975 | 21.81 (19.79)                        | 15.54 (0.44)   | 48.24 (7.67)   |
| 1985 | 33.93 (30.78)                        | 88.64 (2.51)   | 151.52 (24.09)   |
| 1995 | 28.17 (25.56)                        | 54.74 (1.55)   | 91.96 (14.62)  |
| 2000 | 26.51 (24.05)                        | 129.96 (3.68)  | 168.06 (26.72)   |
| 2003 | 29.29 (26.57)                        | 175.87 (4.98)  | 173.35 (27.56)   |

### COAL CONVERSION

Coal is the most abundant fossil fuel, and it will be available long after petroleum and natural gas are scarce. However, because liquids and gases are more desirable than solid fuels, technologies have been, and continue to be, developed to economically convert coal into liquid and gaseous fuels.

Bodley, Vyas, and Talwalker (*Clean Fuels from Coal Symposium II*, Institute of Gas Technology, Chicago, 1975) presented the chart in Fig. 24-3, which shows very simply the different routes from coal to clean gases and liquids.

### Coal Gasification

**GENERAL REFERENCES:** *Fuel Gasification Symp.*, 152d American Chemical Society Mtg., Sept. 1966. *Chemistry of Coal Utilization*, suppl. vol., Lowry (ed.), Wiley, New York, 1963; and 2d suppl. vol., Elliot (ed.), 1981. *Coal Gasification Guidebook: Status, Applications, and Technologies*, Electric Power Research Institute, EPRI TR-102034, Palo Alto, Calif., 1993. *Riegel's Handbook of Industrial Chemistry*, 10th ed., Kent (ed.), Chap. 17, 2003. *Gasification* by Higman and van der Burgt, Elsevier, 2003. "The Case for Gasification" by Stiegel and Ramezan, EM, Dec. 2004, pp. 27-33.

**Background** The advantages of gaseous fuels have resulted in an increased demand for gas and led to the invention of advanced processes for coal gasification. Converting coal to combustible gas has been practiced commercially since the early 19th century. Chapter 17 of *Riegel's Handbook of Industrial Chemistry*, 10th ed., provides a good summary of the early history of coal gasification. Coal-derived gas was distributed in urban areas of the United States for residential and commercial uses until its displacement by lower-cost natural gas, starting in the 1940s. At about that time, development of oxygen-based gasification processes was initiated. An early elevated-pressure gasification process, developed by Lurgi Kohle u Mineralöltechnik GmbH, is still in use. The compositions of gases produced by this and a number of more recent gasification processes are listed in Table 24-10.

**Theoretical Considerations** The chemistry of coal gasification can be approximated by assuming coal is only carbon and considering the most important reactions involved (see Table 24-11). Reaction (24-14), the combustion of carbon with oxygen, which can be assumed to go to completion, is highly exothermic and supplies most of the thermal energy for the other gasification reactions. The oxygen used in the gasifier may come from direct feeding of air or may be high-purity oxygen from an air separation unit. Endothermic reactions (24-16) and (24-17), which represent the conversion of carbon to combustible gases, are driven by the heat energy supplied by reaction (24-14).

Hydrogen and carbon monoxide produced by the gasification reaction react with each other and with carbon. The hydrogenation of carbon to produce methane, reaction (24-15), is exothermic and contributes heat energy. Similarly, methanation of CO, reaction (24-19), can also contribute heat energy. These reactions are affected by the water-gas-shift reaction (24-18), the equilibrium of which controls the extent of reactions (24-16) and (24-17).

Several authors have shown [cf. Gumz, *Gas Producers and Blast Furnaces*, Wiley, New York, 1950; Elliott and von Fredersdorff, *Chemistry of Coal Utilization*, 2d suppl. vol., Lowry (ed.), Wiley, New

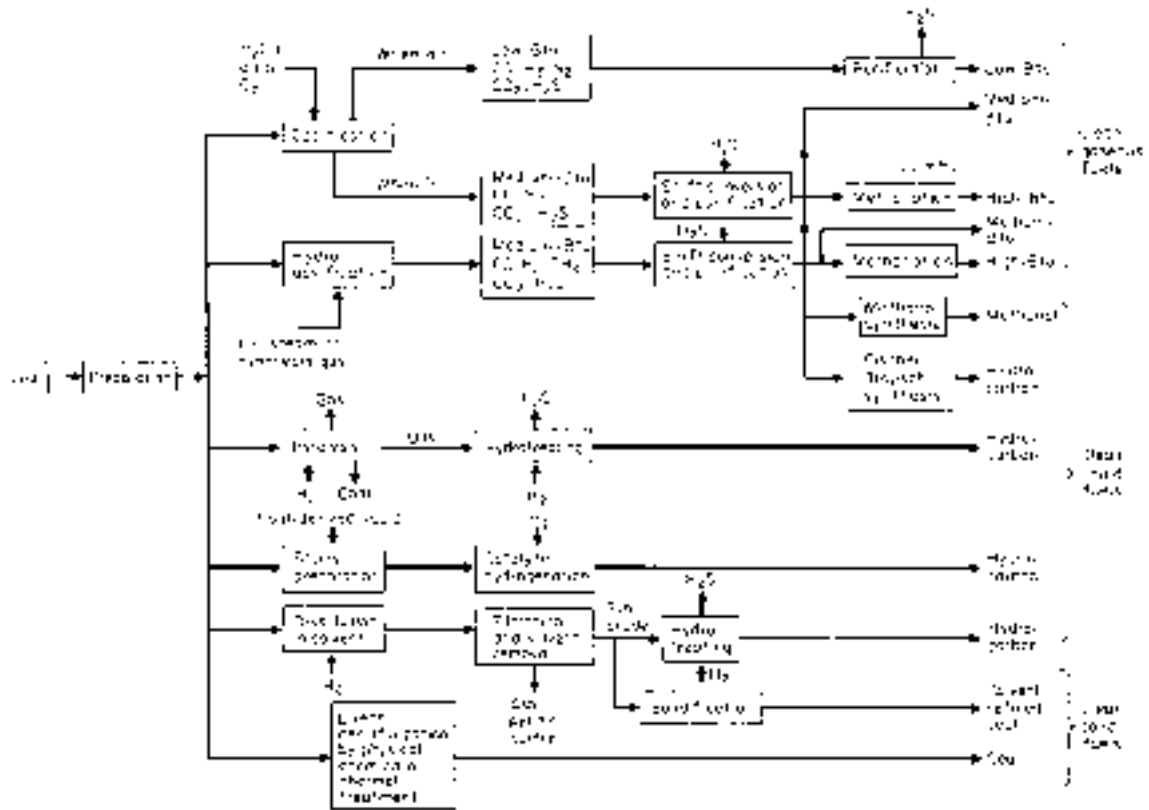

FIG. 24-3 The production of clean fuels from coal. (Based on W. Bodle, K. Vyas, and A. Talwalker; Clean Fuels from Coal Symposium II, Institute of Gas Technology, Chicago, 1975.)

York, 1963] that there are three fundamental gasification reactions: the Boudouard reaction (24-17), the heterogeneous water-gas-shift reaction (24-18), and the hydrogasification reaction (24-15). The equilibrium constants for these reactions are sufficient to calculate equi-

librium for all the reactions listed. Unfortunately, it is not possible to calculate accurate gas composition by using reactions (24-14) to (24-19). One reason is that not all reactions may be in equilibrium. Another reason is that other reactions are taking place. Since gasifica-

tion of coal always involves elevated temperatures, thermal decomposition (pyrolysis) takes place as coal enters the gasification zone of the reactor. Reaction (24-20) treats coal as a hydrocarbon and postulates its thermal disintegration to produce carbon (coke) and methane. Reaction (24-21) illustrates the stoichiometry of hydrogasifying part of the carbon to produce methane.

These reactions can be used to estimate the effect of changes in operating parameters on gas composition. As temperature increases, endothermic reactions are favored over exothermic reactions. Methane production will decrease, and CO production will be favored as reactions are shifted in the direction in which heat absorption takes place. An increase in pressure favors reactions in which the number of moles of products is less than the number of moles of reactants. At higher pressure, production of  $CO_2$  and  $CH_4$  will be favored.

It is generally believed that oxygen reacts completely in a very short distance from the point at which it is mixed or comes in contact with coal or char. The heat evolved acts to pyrolyze the coal, and the char formed then reacts with carbon dioxide, steam, and other gases formed by combustion and pyrolysis. The assumption made in Table 24-11 that the solid reactant is carbon is probably close to correct, but the type of char formed affects the kinetics of gas-solid reactions. The overall reaction is probably rate-controlled below 1273 K (1832°F). Above this temperature, pore diffusion has an overriding effect, and at very high temperatures surface-film diffusion probably controls. For many gasification processes, the reactivity of the char is quite important and can depend on feed coal characteristics, the method of heating, the rate of heating, and particle-gas dynamics.

The importance of these concepts can be illustrated by the extent to which the pyrolysis reactions contribute to gas production. In a moving-bed gasifier, the particle is heated through several distinct thermal zones. In the initial heat-up zone, coal carbonization or devolatilization dominates. In the successively hotter zones, char devolatilization, char gasification, and fixed carbon combustion are the dominant processes. About 17 percent of total gas production occurs during coal devolatilization, and about 23 percent is produced during char devolatilization. The balance is produced during char gasification and combustion.

**Gasifier Types and Characteristics** The three main types of gasifier reactors, moving bed, fluidized bed, and entrained bed, as shown in Fig. 24-4, are all in commercial use. The moving bed is sometimes referred to as a "fixed" bed, because the coal bed is kept at a constant height. These gasifiers can differ in many ways: size, type of coal fed, feed and product flow rates, residence time, and reaction temperature. Gas compositions from the gasifiers discussed below are listed in Table 24-10.

**Moving bed** Depending on the temperature at the base of the coal bed, the ash can either be dry or in the form of molten slag. If excess steam is added, the temperature can be kept below the ash fusion point, in which case the coal bed rests on a rotating grate which allows the dry ash to fall through for removal. To reduce steam usage, a slagging bottom gasifier was developed by British Gas and Lurgi (BGL) in which the ash is allowed to melt and drain off through a slag tap. This gasifier has over twice the capacity per unit of cross-section

area of the dry-bottom gasifier. The BGL technology is offered commercially by Allied Syngas and Advantica.

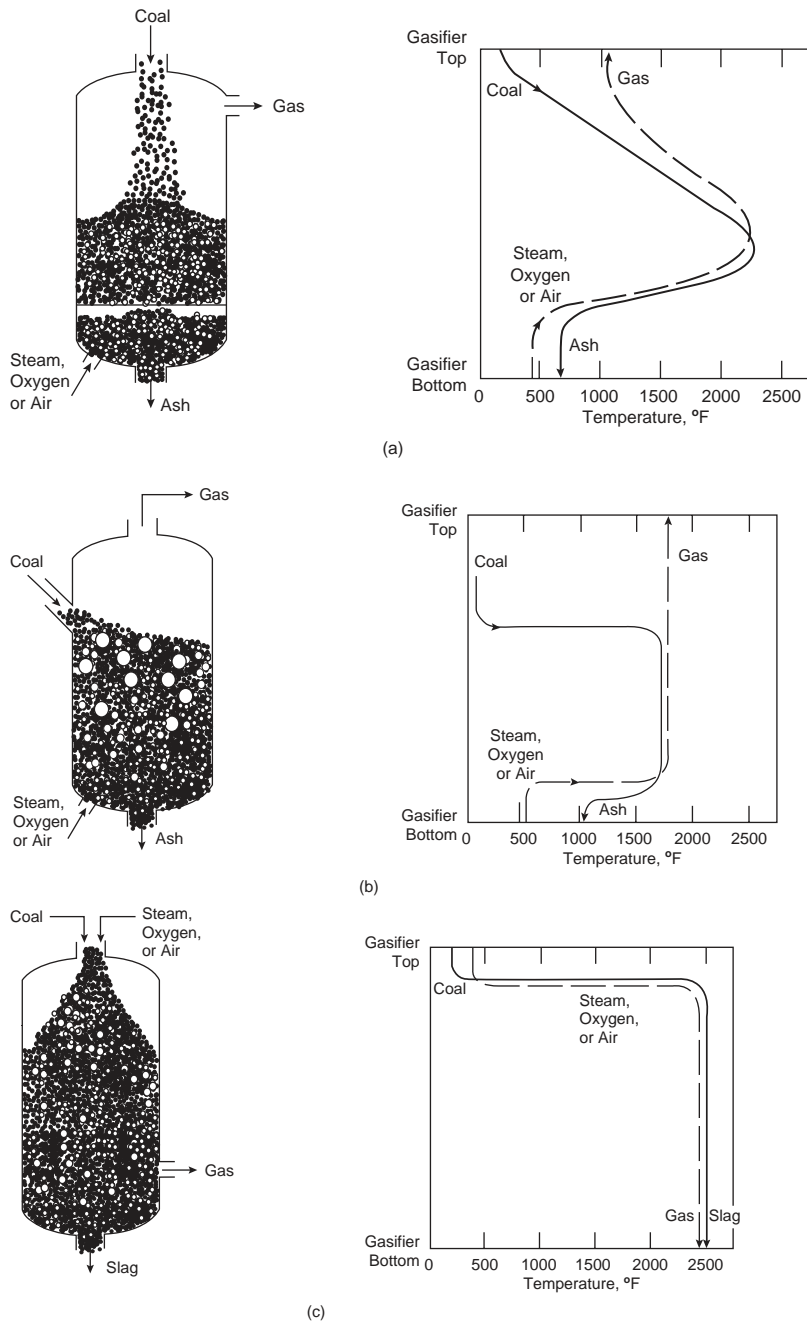

**Fluidized bed** The problem of coal agglomeration is eliminated by a fluidized-bed gasifier developed by GTI. The U-Gas gasification process uses an agglomerating-ash fluidized-bed gasifier in which crushed limestone can be injected with the coal for sulfur capture. Char and ash that exit the gasifier with the product gas are recycled to the hot agglomerating and jetting zone, where temperatures are high enough to pyrolyze fresh coal introduced at that point, gasify the char, and soften the ash particles. The ash particles stick together and fall to the base of the gasifier, where they are cooled and removed. The agglomerating fluid-bed gasifier can be blown by either air or oxygen. Pressurized operation has several advantages: slightly higher methane formation, resulting in higher heating value of the gas; increased heat from the methanation reactions, which reduces the amount of oxygen needed; reduced heat losses through the wall and, consequently, improved efficiency; and higher capacity.

**Entrained bed** The primary example of an oxygen-blown, dry-feed, entrained-flow gasifier is the Shell gasifier. An advantage of Shell coal gasification technology is its ability to process a range of coals, with a wide variety of coals (from brown coal to anthracite) having been successfully tested. As with other entrained-flow gasifiers, disadvantages of the Shell process include a high oxygen requirement and a high waste heat recovery duty. However, the ability to feed dry coal reduces the oxygen requirement below that of single-stage entrained-flow gasifiers that use slurry feed and makes the Shell gasifier somewhat more efficient. The penalty for this small efficiency improvement is a more complex coal-feeding system. Uhde and Shell are marketing this technology.

Two slurry-fed, entrained-flow gasifiers are the Texaco gasifier (now owned by GE) and the E-Gas gasifier (now owned by ConocoPhillips). The Texaco gasifier is similar to the Shell gasifier, except that the coal is fed as a slurry. Reactor exit gas is cooled either by direct water injection or by a radiative cooler directly below the reactor. The E-Gas gasifier differs from other systems in that it uses a two-stage reactor. The bulk of the feed slurry and all the oxygen are sent to the first (horizontal) stage, where the coal is gasified. Hot gas flows into the second (vertical) stage, where the remainder of the coal slurry is injected. Hot fuel gas is cooled in a fire-tube boiler fuel gas cooler.

**Gasification-Based Liquid Fuels and Chemicals** Liquid fuels and chemicals from gasification-based synthesis gas are described in the coal liquefaction section following this section. While the downstream areas of power system and indirect liquefaction plants will differ markedly, the gasification sections will be quite similar and are described in this section.

**Gasification-Based Power Systems** An important driving force for coal gasification process development is the environmental superiority of gasification-based power generation systems, generally referred to as integrated gasification combined-cycle (IGCC) power production (Fig. 24-5). Coal is crushed prior to being fed to a reactor, where it is gasified through contact with steam and air or oxygen. Partial oxidation produces the high-temperature [1033 to 2255 K

**FIG. 24-4** Gasifier types and temperature profiles: (a) fixed bed (dry ash); (b) fluidized bed; (c) entrained flow. (This figure was published in N. Holt and S. Alpert, "Integrated Gasification Combined-Cycle Power," vol. 7, pp. 897-905, in *Encyclopedia of Physical Science and Technology*, 3d ed. Copyright Elsevier, 2002.)

(1400 to 3600°F), depending on the type of gasifier] reducing environment necessary for gasification. The product fuel gas passes through heat recovery and cleanup, where particulates (dust) and sulfur are removed. After cleanup, the fuel gas, composed primarily of hydrogen and carbon oxides, is burned with compressed air and expanded through a gas turbine to generate electricity. Heat is recovered from the turbine's hot exhaust gas to produce steam (at subcritical conditions), which is expanded in a steam turbine for additional electric power generation.

All three basic gasifier types could be incorporated into IGCC plant designs, although to date only entrained-flow gasifiers have actually been deployed. With each gasifier type, the oxidant can be air or oxygen, and the coal can be fed dry or in a slurry. The composition of the fuel gas, as well as its pressure and temperature, is determined by the design of the gasifier and the gas cleanup system.

There are several features of IGCC power systems that contribute to their improved thermal efficiency and environmental superiority compared to a conventional pulverized-coal fired power plant. First, the

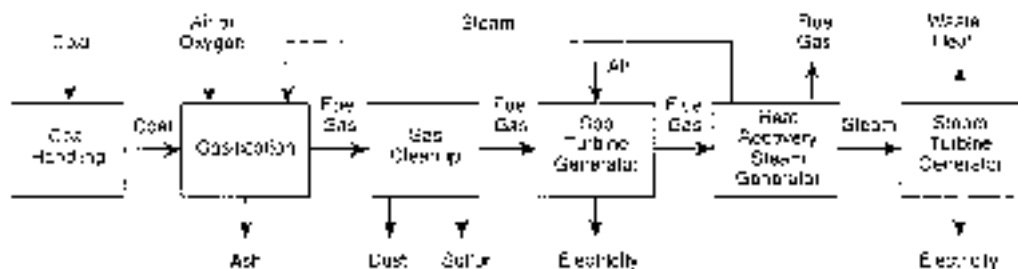

FIG. 24-5 Integrated gasification combined-cycle block diagram.

mass flow rate of gas from a gasifier is about one-fourth that from a combustor, because the gasifier is oxygen-blown and operates substoichiometrically, while the combustor is air-blown and operates with excess air. Because of the elevated operating pressure and the lack of nitrogen dilution, the volumetric gas flow to the sulfur removal system is actually only 0.5 percent to 1 percent of the volumetric flow to the flue gas desulfurization unit; this lowers the capital cost of the gas cleanup system.

Furthermore, the sulfur in coal-derived fuel gas is mainly present as hydrogen sulfide, which is much more easily recovered than the sulfur dioxide in flue gas. Not only can hydrogen sulfide be easily converted to elemental sulfur, a more valuable by-product than the calcium sulfate produced when lime is used to remove sulfur dioxide from flue gas, but also neither lime nor limestone is required. Nitrogen in the coal is largely converted to nitrogen gas or ammonia, which is easily removed by water washing, thus reducing nitrogen oxide emissions when the fuel gas is burned. Carbon dioxide can also be scrubbed from the fuel gas, and if even further reductions in carbon emissions are required, the carbon monoxide in the fuel gas can be converted to hydrogen and carbon dioxide before  $\text{CO}_2$  removal. Finally, it has been estimated that the cost of mercury removal from an IGCC system would be only about one-tenth the cost for a conventional power plant.

Another advantage is that the IGCC system generates electricity by both combustion (Brayton cycle) and steam (Rankine cycle) turbines. The inclusion of the Brayton topping cycle improves efficiency compared to a conventional power plant's Rankine cycle-only generating system. Typically, about two-thirds of the power generated comes from the Brayton cycle and one-third from the Rankine cycle.

**Current Status** There have been substantial advancements in the development of gasification-based power systems during the last two decades. Programs are in place in the United States to support demonstration projects and for conducting research to improve efficiency, cost effectiveness, and environmental performance of IGCC power generation. Two areas of research that are likely to produce significant improvements in coal gasification technology are air separation (oxygen production) and fuel gas cleanup (removal of sulfur, mercury, particulates, and other pollutants).

Gasification technology is being widely used throughout the world. A study conducted in 2004 indicated that there were 156 gasification projects worldwide. Total capacity of the projects in operation was 45,000 MW (thermal) with another 25,000 MW (thermal) in various stages of development. As discussed later, in addition to producing fuel gas for power production, synthesis gas production by gasification is the first step in the indirect liquefaction of coal. Furthermore, gasification of carbonaceous, hydrogen-containing fuels is an effective method of thermal hydrogen production and is considered to be a key technology in the transition to a hydrogen economy. Therefore, the possibility exists for the coproduction of electric power and liquid fuels while sequestering carbon dioxide. Such an option could allow a gasifier in an IGCC system to operate at full capacity at all times, producing fuel gas at times of peak power demand and a mix of fuel gas and synthesis gas at other times.

In 2005, there were four coal-based IGCC power plants in operation in the world: Tampa Electric in Polk County, Florida, based on a Texaco (now GE) gasifier; Wabash repowering project in Indiana, based on E-Gas (now ConocoPhillips E-Gas); and Buggenum in The Netherlands and Puertollano in Spain, both based on Shell gasifiers (N.A.H. Holt, "IGCC Technology—Status, Opportunities, and Issues," *EM*, Dec. 2004, pp. 18–26).

**Cost of Gasification-Based Power Systems** Comparing power options is complicated by the many different parameters that must be considered in making a cost determination: coal cost; coal properties, including sulfur and moisture contents; ambient temperature; degree of process integration; gas turbine model; and gas cleanup method. These, and many other factors, have a significant impact on cost.

While comparison of absolute costs among different power systems is difficult, the costs of the component units are usually within given ranges. For an oxygen-blown IGCC power system, the breakdown of the capital cost for the four component units is: air separation plant, 10 to 15 percent; gasifier including gas cleanup, 30 to 40 percent; combined-cycle power unit, 40 to 45 percent; and balance of plant, 5 to 10 percent. The breakdown of the cost of electricity is: capital charge, 52 to 56 percent; operating and maintenance, 14 to 17 percent; and fuel, 28 to 32 percent.

One of the main challenges to the development and deployment of IGCC power plants has been that the capital cost was significantly higher than that of a natural-gas-fired generating unit, thereby negating the fuel cost savings. However, if natural gas prices remain substantially above \$4.75/GJ (\$5.00/10<sup>6</sup> Btu), that should no longer be the case. Moreover, capital costs of IGCC power plants are likely to decline considerably as more of these facilities are built, standard designs are developed, and economies of scale are realized.

### Coal Liquefaction

**Background** Coal liquefaction denotes the process of converting solid coal to a liquid fuel. The primary objective of any coal liquefaction process is to increase the hydrogen-to-carbon molar ratio. For a typical bituminous coal, this ratio is about 0.8, while for light petroleum it is about 1.8. A secondary objective is to remove sulfur, nitrogen, oxygen, and ash so as to produce a nearly pure hydrocarbon. There are several ways to accomplish liquefaction: (1) pyrolysis, (2) direct hydrogenation of the coal at elevated temperature and pressure, (3) hydrogenation of coal slurried in a solvent, and (4) gasification of coal to produce synthesis gas (a mixture of hydrogen and carbon monoxide, also referred to as syngas) followed by the use of Fischer-Tropsch (F-T) chemistry to produce liquid products. The first three of these approaches are generally referred to as direct liquefaction, in that the coal is directly converted to a liquid. The fourth approach is termed indirect liquefaction, because the coal is first converted to an intermediate product.

**Pyrolysis** In pyrolysis, coal is heated in the absence of oxygen to drive off volatile components, leaving behind a solid residue enriched in carbon and known as char or coke. Most coal pyrolysis operations are for the purpose of producing metallurgical coke, with the liquids

produced being considered only as a by-product. However, some small-scale work has been done to maximize liquids production by heating the coal at carefully controlled conditions of temperature vs. time, usually in several stages. Although capable of producing a significant liquid yield, this approach has two major drawbacks. First, the liquids produced are of low quality and require significant upgrading to convert them to salable products. Second, a large fraction of the original heating value of the coal remains in the char, which must be profitably marketed to make the pyrolysis process economically feasible. Two processes that reached a high state of development were the COED process developed by FMC Corporation, which used a series of fluidized beds operating at successively higher temperatures, and the TOSCOAL process, which used a horizontal rotating kiln.

**Direct Hydrogenation** In direct hydrogenation, pulverized coal is contacted with hydrogen at carefully controlled conditions of temperature and pressure. The hydrogen reacts with the coal, converting it to gaseous and liquid products. In some cases the coal is impregnated with a catalyst before being introduced into the reactor. Again, small-scale experiments have been successfully conducted. However, the major difficulty with this approach is scale-up to commercial size. Significant technical problems exist in feeding a large volume of powdered coal (powdered coal is necessary to provide a large surface area for reaction) into a reactor at high pressure, heating it to the desired temperature, and then quenching the products.

**Direct Liquefaction of Coal** Figure 24-6 presents a simplified process flow diagram of a typical direct coal liquefaction plant using coal slurry hydrogenation. Coal is ground and slurried with a process-derived solvent, mixed with a hydrogen-rich gas stream, preheated, and sent to a one- or two-stage liquefaction reactor system. In the reactor(s), the organic fraction of the coal dissolves in the solvent, and the dissolved fragments react with hydrogen to form liquid and gaseous products. Sulfur in the coal is converted to hydrogen sulfide,

nitrogen is converted to ammonia, and oxygen is converted to water. The reactor products go to vapor/liquid separation. The gas is cleaned and, after removal of a purge stream to prevent buildup of inerts, mixed with fresh hydrogen and recycled. The liquid is sent to fractionation for recovery of distillates. Heavy gas-oil is recycled as process solvent, and vacuum bottoms are gasified for hydrogen production. Ash from the gasifier is sent to disposal. Heavy direct liquefaction products contain polynuclear aromatics and are potentially carcinogenic. However, this problem can be avoided by recycling to extinction all material boiling above the desired product endpoint.

**Direct Liquefaction Kinetics** Hydrogenation of coal in a slurry is a complex process, the mechanism of which is not fully understood. It is generally believed that coal first decomposes in the solvent to form free radicals which are then stabilized by extraction of hydrogen from hydroaromatic solvent molecules, such as tetralin. If the solvent does not possess sufficient hydrogen transfer capability, the free radicals can recombine (undergo retrograde reactions) to form heavy, nonliquid molecules. A greatly simplified model of the liquefaction process is shown below.

Many factors affect the rate and extent of coal liquefaction, including temperature, hydrogen partial pressure, residence time, coal type and analysis, solvent properties, solvent-to-coal ratio, ash composition, and the presence or absence of a catalyst. Many kinetic expressions have appeared in the literature, but since they are generally specific to a particular process, they will not be listed here. In general, liquefaction is

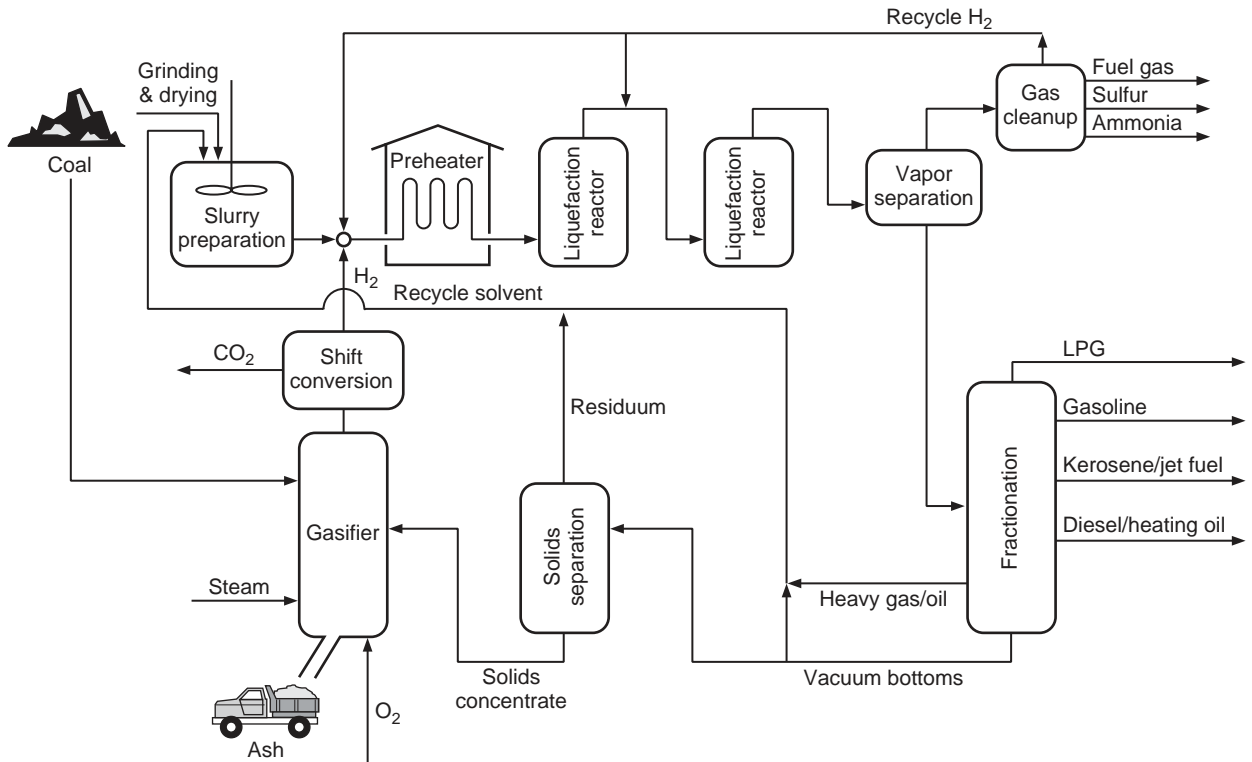

FIG. 24-6 Direct liquefaction of coal.

promoted by increasing the temperature, hydrogen partial pressure, and residence time. However, if the temperature is too high, gas yield is increased and coking can occur. Solvent-to-coal ratio is important. If the ratio is too low, there will be insufficient hydrogen transfer activity; on the other hand, if the ratio is high, a larger reactor will be necessary to provide the required residence time. Typical operating conditions are:

|                       |                                |
|-----------------------|--------------------------------|
| Temperature           | 670–730 K (750–850°F)          |
| Pressure              | 10.3–20.7 MPa (1500–3000 psia) |
| Residence time        | 0.5 h                          |
| Solvent-to-coal ratio | 1.5–2 kg/kg (1.5–2 lb/lb)      |

For the most highly developed processes, maf coal conversion can be as high as 90 to 95 % with a C<sub>4</sub>+ distillate yield of 60 to 75 wt % and a hydrogen consumption of 5 to 7 wt %. When an external catalyst is used, it is typically some combination of cobalt, nickel, and molybdenum on a solid acid support, such as silica alumina. In slurry hydrogenation processes, catalyst life is typically fairly short because of the large number of potential catalyst poisons present in the system.

Several variations of the slurry hydrogenation process, depicted in Fig. 24-6 and discussed below, were tested at pilot-plant scale. Table 24-12 presents typical operating conditions and yields for these processes.

The *SRC-I process*, developed by the Pittsburg & Midway Coal Mining Co. in the early 1960s, was not really a liquefaction process; rather, it was designed to produce a solid fuel for utility applications. Only enough liquid was produced to keep the process in solvent balance. The bottoms product was subjected to filtration or solvent extraction to remove ash and then solidified to produce a low-ash, low-sulfur substitute for coal. However, the value of the product was not high enough to make this process economically viable.

The *SRC-II process*, developed by Gulf Oil Corp., was an improved version of the SRC-I process, designed to produce more valuable liquid products, rather than a solid. The major difference between SRC-II and the typical process described above was the recycle of a portion of the fractionator bottoms to the slurry feed tank. This increased the ash content of the reactor feed. This ash, particularly the iron pyrites in the ash, acted as a catalyst and improved product yield and quality.

The *Exxon Donor Solvent (EDS) Process*, developed by the Exxon Research and Engineering Co., differed from the typical process in that, before being recycled, the solvent was hydrogenated in a fixed-bed reactor using a hydrotreating catalyst, such as cobalt or nickel molybdate. Exxon found that use of this hydrogen donor solvent with carefully controlled properties improved process performance. Exxon developed a solvent index, based on solvent properties, which correlated with solvent effectiveness.

The *H-Coal Process*, based on H-Oil technology, was developed by Hydrocarbon Research, Inc. (HRI). The heart of the process was a three-phase, ebullated-bed reactor in which catalyst pellets were fluidized by the upward flow of slurry and gas through the reactor. The reactor contained an internal tube for recirculating the reaction mixture to the bottom of the catalyst bed. Catalyst activity in the reactor was maintained by the withdrawal of small quantities of spent catalyst and the addition of fresh catalyst. The addition of a catalyst to the reactor is the main feature which distinguishes the H-Coal Process from the typical process.

*Two-stage liquefaction* is an advanced process concept that provides higher yields of better quality products by carrying out the coal solution and the hydrogenation/hydrocracking steps in separate reactors whose conditions are optimized for the reaction that is occurring. Either or both reactors may be catalytic. Slurry catalysts have been tested, in addition to the more conventional supported catalysts, as a means of simplifying reactor design and removing process constraints. The U.S. Department of Energy and its private sector collaborators, Hydrocarbon Technologies, Inc., and others, have advanced the development of the two-stage direct liquefaction process to commercialization status during the last two decades. Coal-derived product quality has been improved dramatically (less than 50 ppm nitrogen content, for example) through the addition of in-line fixed-bed hydrotreating of the product stream.

In *coal-oil coprocessing*, coal is slurried in petroleum residuum rather than in recycle solvent, and both the coal and petroleum components are converted to high-quality fuels in the slurry reactor. This variation offers the potential for significant cost reduction by eliminating or

<sup>g</sup>C<sub>4</sub> is excluded.

<sup>h</sup>Unreacted coal is included.

<sup>i</sup>"Unreacted coal" is actually insoluble organic matter remaining after reaction.

reducing recycle streams. More importantly, fresh hydrogen requirements are reduced, because the petroleum feedstock has a higher initial hydrogen content than coal. As a result, plant capital investment is reduced substantially. Other carbonaceous materials, such as municipal waste, plastics, cellulose, and used motor oils, might also serve as cofeedstocks with coal in this technology.

**Commercial Operations** The world's only commercial-scale direct coal liquefaction plant, located in the Inner Mongolia Autonomous Region of China, was dedicated in 2004. The plant is scheduled to begin production in 2007. The first train of the first phase of the Shenhua Direct Coal Liquefaction Plant will liquefy 2,100,000 Mg/a (2,315,000 ton/yr) of coal from the Shangwan Mine in the Shenhua coal field of Inner Mongolia. The plant will use a combination of technologies developed in the United States, Japan, and Germany with modifications and enhancements developed in China. The first train will use a two-stage reactor system and include an in-line hydrotreater and produce 591,900 Mg/a (652,460 ton/yr) of diesel; 174,500 Mg/a (192,350 ton/yr) of naphtha; 70,500 Mg/a (77,710 ton/yr) of LPG; and 8300 Mg/a (9150 ton/yr) of ammonia. When completed, the plant will include 10 trains producing approximately 10,000,000 Mg/a (11,000,000 ton/yr) of oil products.

Unlike the processes described above, *indirect liquefaction* is not limited to coal but may be performed using any carbonaceous feed, such as natural gas, petroleum residues, petroleum coke, coal, and biomass. Figure 24-7 presents a simplified process flow diagram for a typical indirect liquefaction process using coal as the feedstock. The syngas is produced in a gasifier (see the description of coal gasifiers earlier in this section), which partially combusts the coal or other feed at high temperature [1500 to 1750 K (2200 to 2700°F)] and moderate pressure [2 to 4 MPa (300 to 600 psia)] with a mixture of oxygen (or air) and steam. In addition to H<sub>2</sub> and CO, the raw synthesis gas contains other constituents, such as CO<sub>2</sub>, H<sub>2</sub>S, NH<sub>3</sub>, N<sub>2</sub>, H<sub>2</sub>O, and CH<sub>4</sub>, as well as particulates and, with some gasifiers, tars.

The syngas leaving the gasifier is cooled and passed through particulate removal equipment. Following this, depending on the requirements of the syngas conversion process, it may be necessary to adjust the H<sub>2</sub>/CO ratio. Modern high-efficiency gasifiers typically produce syngas with the H<sub>2</sub>/CO molar ratio between 0.45 and 0.7, which is lower than the stoichiometric ratio of about 2 for F-T synthesis or methanol production. Some F-T catalysts, particularly iron catalysts, possess water-gas shift conversion activity and permit operation with a low H<sub>2</sub>/CO ratio [see reaction (24-25)]. Others, such as cobalt catalysts, possess little shift activity and require adjustment of the H<sub>2</sub>/CO ratio before the syngas enters the synthesis reactor.

After shift conversion (if required), acid gases (CO<sub>2</sub> and H<sub>2</sub>S) are scrubbed from the synthesis gas. A guard chamber is sometimes used to remove the last traces of H<sub>2</sub>S, since F-T catalysts are generally very sensitive to sulfur poisoning. The cleaned gas is sent to the synthesis reactor, where it is converted at moderate temperature and pressure, typically 498 to 613 K (435 to 645°F) and 1.5 to 6.1 MPa (220 to 880 psia). Products, whose composition depends on operating conditions, the catalyst employed, and the reactor design, include saturated hydrocarbons (mainly straight chain paraffins from methane through n-C<sub>30</sub> and higher), oxygenates (methanol, higher alcohols, ethers), and olefins.

**Fischer-Tropsch Synthesis** The best-known technology for producing hydrocarbons from synthesis gas is the Fischer-Tropsch synthesis. This technology was first demonstrated in Germany in 1902 by Sabatier and Senderens when they hydrogenated carbon monoxide (CO) to methane, using a nickel catalyst. In 1926 Fischer and Tropsch were awarded a patent for the discovery of a catalytic technique to convert synthesis gas to liquid hydrocarbons similar to petroleum.

The basic reactions in the Fischer-Tropsch synthesis are:  
Paraffins formation:

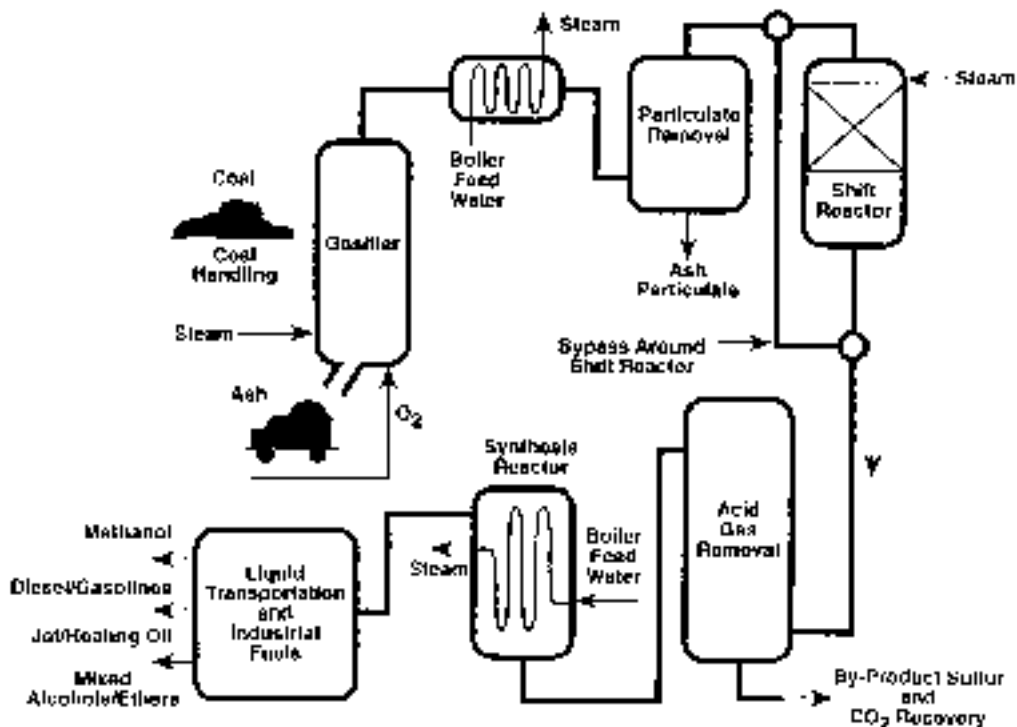

FIG. 24-7 Indirect liquefaction of coal.

## 24-20 ENERGY RESOURCES, CONVERSION, AND UTILIZATION

Olefins formation:

Alcohols formation:

Other reactions may also occur during the Fischer-Tropsch synthesis, depending on the catalyst employed and the conditions used:

Water-gas shift:

Boudouard disproportionation:

Surface carbonaceous deposition:

Catalyst oxidation-reduction:

Bulk carbide formation:

where M represents a catalytic metal atom.

The production of hydrocarbons using traditional F-T catalysts is governed by chain growth (polymerization) kinetics. The theoretical equation describing the distribution of hydrocarbon products, commonly referred to as the Anderson-Schulz-Flory (ASF) equation, is

$$\log \frac{W_n}{n} = n \log \alpha + \log \frac{(1-\alpha)^2}{\alpha} \quad (24-31)$$

where  $W_n$  is the weight fraction of products with carbon number  $n$ , and  $\alpha$  is the chain growth probability, i.e., the probability that a carbon chain on the catalyst surface will grow by adding another carbon atom rather than desorb from the catalyst surface and terminate. In deriving Eq. (24-31),  $\alpha$  is assumed to be independent of chain length. However,  $\alpha$  is dependent on temperature, pressure,  $\text{H}_2/\text{CO}$  ratio, and catalyst composition. As  $\alpha$  increases, the average carbon number of the product also increases. When  $\alpha$  equals 0, methane is the only product formed. As  $\alpha$  approaches 1, the product becomes predominantly wax. In practice,  $\alpha$  is not really independent of chain length. Methane production, particularly with cobalt catalysts, is typically higher than predicted; and  $\text{C}_2$  yield is often lower. Some investigators have found a significant deviation from the ASF distribution for higher-carbon-number products and have proposed a dual alpha mechanism to explain their results.

Figure 24-8 provides a graphical representation of Eq. 24-32 showing the weight fraction of various products as a function of  $\alpha$ . This figure shows that there is a particular  $\alpha$  that will maximize the yield of any desired product, such as gasoline or diesel fuel. Based on the ASF equation, the weight fraction of material between carbon numbers  $m$  and  $n$  inclusive is given by

$$W_{mn} = m\alpha^{m-1} - (m-1)\alpha^m - (n+1)\alpha^n + n\alpha^{n+1} \quad (24-32)$$

The  $\alpha$  to maximize the yield of the carbon number range from  $m$  to  $n$  is given by

$$\alpha_{\text{opt}} = \left(\frac{m^2 - m}{n^2 + n}\right)^{1/(n-m+1)} \quad (24-33)$$

Additional gasoline and diesel fuel can be produced through further refining, such as hydrocracking or catalytic cracking of the wax product or polymerization of light olefins.

**F-T Catalysts** The patent literature is replete with recipes for the production of F-T catalysts, with most formulations being based on iron, cobalt, or ruthenium, typically with the addition of some promoter(s). Nickel is sometimes listed as a F-T catalyst, but nickel has too much hydrogenation activity and produces mainly methane. In practice, because of the cost of ruthenium, commercial plants use either cobalt-based or iron-based catalysts. Cobalt is usually deposited on a refractory oxide support, such as alumina, silica, titania, or zirconia. Iron is typically not supported and may be prepared by precipitation.

FIG. 24-8 Product yield in Fischer-Tropsch synthesis.

Of the large number of promoters listed in patents, rhenium or one of the noble metals may be used to promote cobalt, and iron is often promoted with potassium.

**Reactor Design** The F-T reaction is highly exothermic and, for hydrogen-rich syngas, can be symbolically represented by

For CO-rich syngas, the overall reaction is

Because of the high heat release, adequate heat removal from the reactor is critical. High temperatures result in high yields of methane as well as coking and sintering of the catalyst. Three types of reactors (tubular fixed bed, fluidized bed, and slurry) provide good temperature control, and all three types are being used for synthesis gas conversion. The first plants used tubular or plate-type fixed-bed reactors. Later, SASOL, in South Africa, used fluidized-bed reactors, and most recently, slurry reactors have come into use. Fluid bed reactors are limited to the production of products that are volatile at reactor operating conditions. Nonvolatile products accumulate on the catalyst and destroy its fluidizing properties.

F-T reactor operations can be classified into two categories: high-temperature, 613 K (645°F), or low-temperature, 494-544 K (430 to 520°F). The Synthol reactor developed by SASOL is typical of high-temperature operation. Using an iron-based catalyst, this reactor produces a very good gasoline having high olefinicity and a low boiling range. The olefin fraction can readily be oligomerized to produce diesel fuel. Low-temperature operation, typical of fixed-bed reactors, produces a much more paraffinic and straight-chain product. The chain growth parameter can be tailored to give the desired product selectivity. The primary diesel fraction, as well as the diesel-range product from hydrocracking of the wax, is an excellent diesel fuel.

**Chemicals from Syngas** A wide range of products can be produced from syngas. These include such chemicals as methanol, ethanol, isobutanol, dimethyl ether, dimethyl carbonate, and many other chemicals. Typical methanol-producing reactions are

Once methanol is produced, it can be converted to an extensive range of materials. The following reactions illustrate some of the chemicals of major importance that can be made from methanol. Among these are dimethyl ether, acetic acid, methyl acetate, acetic anhydride, vinyl acetate, formaldehyde, and methyl tertiarybutyl ether (MTBE).

Reaction (24-38) can occur in parallel with the methanol-producing reactions, thereby overcoming the equilibrium limitation on methanol formation. Higher alcohols can also be formed, as illustrated by reaction (24-24), which can generate either linear or branched alcohols, depending on the catalyst used and the operating conditions. The production of methyl acetate, reaction (24-40), from synthesis gas is currently being practiced commercially. Following methanol synthesis, one-half of the methanol is reacted with carbon monoxide to form acetic acid, which is reacted with the rest of the methanol to form methyl acetate.

Methyl acrylate and methyl methacrylate, which are critical to the production of polyesters, plastics, latexes, and synthetic lubricants, can also be produced. For example, methyl methacrylate can be produced from propylene and methanol:

**Commercial Operations** The only commercial indirect coal liquefaction plants for the production of transportation fuels are operated by SASOL in South Africa. Construction of the original plant was begun in 1950, and operations began in 1955. This plant employed both fixed-bed (Arge) and entrained-bed (Synthol) reactors. The fixed-bed reactors have been converted to natural gas, and the Synthol reactors have been replaced by advanced fixed-fluidized bed reactors. Two additional plants that employ dry-ash Lurgi Mark IV coal gasifiers and entrained-bed (Synthol) reactors for synthesis gas conversion were constructed with start-ups in 1980 and 1983. In addition to producing a significant fraction of South Africa's transportation fuel requirements, these plants produce more than 120 other products from coal.

SASOL and others, including Exxon, Statoil, Air Products and Chemicals, Inc., and the U.S. Department of Energy, have engaged in the development of slurry bubble column reactors for F-T and oxygenate synthesis. SASOL commissioned a 5-m-diameter slurry reactor in 1993, which doubled the wax capacity of the SASOL I facility. The development work on slurry reactors shows that they have several advantages over competing reactor designs: (1) excellent heat-transfer capability resulting in nearly isothermal reactor operations, (2) high catalyst and reactor productivity, (3) ease of catalyst addition and withdrawal, (4) simple construction, and (5) ability to process hydrogenlean synthesis gas successfully. Because of the small particle size of the catalyst used in slurry reactors, effective separation of catalyst from the products can be difficult but is crucial to successful operation.

The United States has two commercial facilities that convert coal to fuels or chemicals via a syngas intermediate. The Great Plains Synfuels

Plant, located in Beulah, N. Dak., and operated by Dakota Gasification Company (DGC), produces synthetic natural gas (SNG) from North Dakota lignite. Fourteen Lurgi dry-ash gasifiers in the plant convert approximately 15,400 Mg/d (17,000 U.S. ton/day) of lignite into syngas which is methanated to about  $4.7 \times 10^6 \text{ N}\cdot\text{m}^3$  ( $166 \times 10^6 \text{ std ft}^3$ ) of pipeline-quality gas. Aromatic naphtha and tar oil are also produced in the gasification section. The plant operates at 120 percent of its original design capacity. In addition to SNG, a wide assortment of other products are produced and sold (anhydrous ammonia, ammonium sulfate, phenol, cresylic acid, naphtha, krypton and xenon gases, liquid nitrogen, and carbon dioxide).

Eastman Chemical Company has operated a coal-to-methanol plant in Kingsport, Tenn., since 1983. Two Texaco gasifiers (one is a backup) process 34 Mg/h (37 U.S. ton/h) of coal to synthesis gas. Using ICI methanol technology, the synthesis gas is converted to methanol, which is an intermediate in the production of methyl acetate and acetic acid. The plant produces about 225,000 Mg/a (250,000 U.S. ton/yr) of acetic anhydride. As part of the DOE Clean Coal Technology Program, Air Products and Chemicals, Inc., and Eastman Chemical Company constructed and operated a 9.8 Mg/h (260 U.S. ton/d) slurry-phase reactor for the conversion of synthesis gas to methanol.

Despite the success of SASOL, most of the commercial interest in Fischer-Tropsch synthesis technology is based on natural gas, as this represents a way to bring remote gas deposits to market using conventional tankers. In 1985, Mobil commercialized its Methanol-to-Gasoline (MTG) technology in New Zealand, natural gas being the feedstock. This fixed-bed process converted synthesis gas to 4000 Mg/d (4400 U.S. ton/day) of methanol; the methanol could then be converted to 2290 m<sup>3</sup>/d (14,400 bbl/d) of gasoline. Owing to economic factors, the plant was used primarily for the production of methanol; it has been shut down due to an insufficient gas supply.

Shell Gas B.V. constructed a 1987 m<sup>3</sup>/d (12,500 bbl/d) F-T plant in Malaysia that started operations in 1994. The Shell Middle Distillate Synthesis (SMDS) process uses natural gas as the feedstock to fixed-bed reactors containing cobalt-based catalyst. The heavy hydrocarbons from the F-T reactors are converted to distillate fuels by hydrocracking and hydroisomerization. The quality of the products is very high, the diesel fuel having a cetane number in excess of 75 with no sulfur.

The largest F-T facility based on natural gas is the Moss gas plant located in Mossel Bay, South Africa. Natural gas is converted to synthesis gas in a two-stage reformer and subsequently converted to hydrocarbons by SASOL's Synthol technology. The plant, commissioned in 1992, has a capacity of 7155 m<sup>3</sup>/d (45,000 bbl/d).

In addition to these commercial facilities, several companies have smaller-scale demonstration facilities, generally with capacities of a few hundred barrels per day of liquid products. For example, Exxon Research and Engineering Company developed a process for converting natural gas to high-quality refinery feedstock, the AGC-21 Advanced Gas Conversion Process. The technology involves three highly integrated process steps: fluid-bed synthesis gas generation; slurry-phase Fischer-Tropsch synthesis; and mild fixed-bed hydroisomerization. The process was demonstrated in the early 1990s with a slurry-phase reactor having a diameter of 1.2 m (4 ft) and a capacity of about 32 m<sup>3</sup>/d (200 bbl/d).

## COMBUSTION BACKGROUND

### Basic Principles

**Theoretical Oxygen and Air for Combustion** The amount of oxidant (oxygen or air) just sufficient to burn the carbon, hydrogen, and sulfur in a fuel to carbon dioxide, water vapor, and sulfur dioxide is the *theoretical* or *stoichiometric oxygen or air* requirement. The chemical equation for complete combustion of a fuel is

$x, y, z,$  and  $w$  being the number of atoms of carbon, hydrogen, oxygen, and sulfur, respectively, in the fuel. For example, 1 mol of methane ( $\text{CH}_4$ ) requires 2 mol of oxygen for complete combustion to 1 mol of carbon dioxide and 2 mol of water. If air is the oxidant, each mol of oxygen is accompanied by 3.76 mol of nitrogen.

The volume of theoretical oxygen (at 0.101 MPa and 298 K) needed to burn any fuel can be calculated from the ultimate analysis of the fuel as follows:

$$24.45 \left( \frac{C}{12} + \frac{H}{4} - \frac{O}{32} + \frac{S}{32} \right) = m^3 \text{O}_2/\text{kg fuel} \quad (24-47)$$

where  $C, H, O,$  and  $S$  are the decimal weights of these elements in 1 kg of fuel. (To convert to  $\text{ft}^3$  per lb of fuel, multiply by 16.02.) The mass of oxygen (in kg) required can be obtained by multiplying the volume by 1.31. The volume of theoretical air can be obtained by using a coefficient of 116.4 in Eq. (24-47) in place of 24.45.

Figure 24-9 gives the theoretical air requirements for a variety of combustible materials on the basis of fuel higher heating value (HHV). If only the fuel lower heating value is known, the HHV can be calculated from Eq. (24-5). If the ultimate analysis is known, Eq. (24-4) can be used to determine HHV.

**Excess Air for Combustion** More than the theoretical amount of air is necessary in practice to achieve complete combustion. This excess air is expressed as a percentage of the theoretical air amount. The *equivalence ratio* is defined as the ratio of the actual fuel-air ratio to the stoichiometric fuel-air ratio. Equivalence ratio values less than 1.0 correspond to fuel-lean mixtures. Conversely, values greater than 1.0 correspond to fuel-rich mixtures.

**Products of Combustion** For lean mixtures, the *products of combustion* (POC) of a sulfur-free fuel consist of carbon dioxide, water vapor, nitrogen, oxygen, and possible small amounts of carbon monoxide and unburned hydrocarbon species. Figure 24-10 shows the effect of fuel-air ratio on the flue gas composition resulting from the combustion of natural gas. In the case of solid and liquid fuels, the POC may also include solid residues containing ash and unburned carbon particles.

Equilibrium combustion product compositions and properties may be readily calculated using thermochemical computer codes which minimize the Gibbs free energy and use thermodynamic databases containing polynomial curve-fits of physical properties. Two widely used versions are those developed at NASA Lewis (Gordon and McBride, NASA SP-273, 1971) and at Stanford University (Reynolds, STANJAN Chemical Equilibrium Solver, Stanford University, 1987).

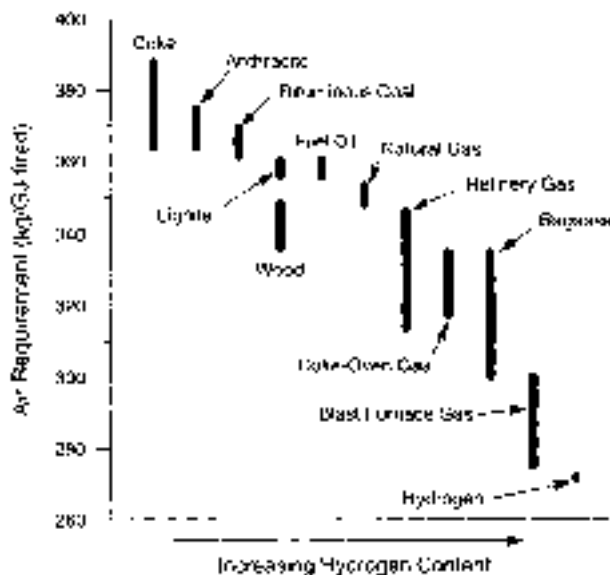

FIG. 24-9 Combustion air requirements for various fuels at zero excess air. To convert from kg air/GJ fired to lb air/10<sup>6</sup> Btu fired, multiply by 2.090.

FIG. 24-10 Effect of fuel-air ratio on flue-gas composition for a typical U.S. natural gas containing 93.9%  $\text{CH}_4$ , 3.2%  $\text{C}_2\text{H}_6$ , 0.7%  $\text{C}_3\text{H}_8$ , 0.4%  $\text{C}_4\text{H}_{10}$ , 1.5%  $\text{N}_2$  and 1.1%  $\text{CO}_2$  by volume.

**Flame Temperature** The heat released by the chemical reaction of fuel and oxidant heats the POC. Heat is transferred from the POC, primarily by radiation and convection, to the surroundings, and the resulting temperature in the reaction zone is the flame temperature. If there is no heat transfer to the surroundings, the flame temperature equals the theoretical, or adiabatic, flame temperature.

Figure 24-11 shows the *available heat* in the products of combustion for various common fuels. The available heat is the total heat

FIG. 24-11 Available heats for some typical fuels. The fuels are identified by their gross (or higher) heating values. All available heat figures are based upon complete combustion and fuel and air initial temperature of 298 K (60°F). To convert from MJ/Nm<sup>3</sup> to Btu/ft<sup>3</sup>, multiply by 26.84. To convert from MJ/dm<sup>3</sup> to Btu/gal, multiply by 3585.

TABLE 24-13 Combustion Characteristics of Various Fuels\*

\*For combustion with air at standard temperature and pressure. These flame temperatures are calculated for 100 percent theoretical air, disassociation considered. Data from *Gas Engineers Handbook*, Industrial Press, New York, 1965.

†Flame temperatures are theoretical—calculated for stoichiometric ratio, dissociation considered.

released during combustion minus the flue-gas heat loss (including the heat of vaporization of any water formed in the POC).

**Flammability Limits** There are both upper (or rich) and lower (or lean) limits of flammability of fuel-air or fuel-oxygen mixtures. Outside these limits, a self-sustaining flame cannot form. Flammability limits for common fuels are listed in Table 24-13.

**Flame Speed** Flame speed is defined as the velocity, relative to the unburned gas, at which an adiabatic flame propagates normal to itself through a homogeneous gas mixture. It is related to the combustion reaction rate and is important in determining burner flashback and blow-off limits. In a premixed burner, the flame can *flash back* through the flameholder and ignite the mixture upstream of the burner head if the mixture velocity at the flameholder is lower than the flame speed. Conversely, if the mixture velocity is significantly higher than the flame speed, the flame may not stay attached to the flameholder and is said to *blow off*. Flame speed is strongly dependent on fuel/air ratio, passing from nearly zero at the lean limit of flammability through a maximum and back to near zero at the rich limit of flammability. Maximum flame speeds for common fuels are provided in Table 24-13.

**Pollutant Formation and Control in Flames** Key combustion-generated air pollutants include nitrogen oxides (NO<sub>x</sub>), sulfur oxides (principally SO<sub>2</sub>), particulate matter, carbon monoxide, and unburned hydrocarbons.

**Nitrogen Oxides** Three reaction paths, each having unique characteristics (see Fig. 24-12), are responsible for the formation of NO<sub>x</sub> during combustion processes: (1) *thermal* NO<sub>x</sub>, which is formed by the combination of atmospheric nitrogen and oxygen at high temperatures; (2) *fuel* NO<sub>x</sub>, which is formed from the oxidation of fuel-bound nitrogen; and (3) *prompt* NO<sub>x</sub>, which is formed by the reaction of fuel-derived hydrocarbon fragments with atmospheric nitrogen. (NO<sub>x</sub> is used to refer to NO + NO<sub>2</sub>. NO is the primary form in combustion products [typically 95 percent of total NO<sub>x</sub>]. NO is subsequently oxidized to NO<sub>2</sub> in the atmosphere.)

**Thermal NO<sub>x</sub>** The formation of thermal NO<sub>x</sub> is described by the Zeldovich mechanism:

The first of these reactions is the rate-limiting step. Assuming that O and O<sub>2</sub> are in partial equilibrium, the NO formation rate can be expressed as follows:

$$\frac{d[\text{NO}]}{dt} = A[\text{N}_2][\text{O}_2]^{1/2} \exp\left(\frac{-E}{RT}\right) \quad (24-51)$$

As indicated, the rate of NO formation increases exponentially with temperature, and, of course, oxygen and nitrogen must be available for thermal NO<sub>x</sub> to form. Thus, thermal NO<sub>x</sub> formation is rapid in high-temperature lean zones of flames.

**Fuel NO<sub>x</sub>** Fuel-bound nitrogen (FBN) is the major source of NO<sub>x</sub> emissions from combustion of nitrogen-bearing fuels such as heavy oils, coal, and coke. Under the reducing conditions surrounding the burning droplet or particle, the FBN is converted to fixed nitrogen species such as HCN and NH<sub>3</sub>. These, in turn, are readily oxidized to form NO if they reach the lean zone of the flame. Between 20 and 80 percent of the bound nitrogen is typically converted to NO<sub>x</sub>, depending on the design of the combustion equipment. With prolonged exposure (order of 100 ms) to high temperature and reducing conditions, however, these fixed nitrogen species may be converted to molecular nitrogen, thus avoiding the NO formation path.

**Prompt NO<sub>x</sub>** Hydrocarbon fragments (such as C, CH, CH<sub>2</sub>) may react with atmospheric nitrogen under fuel-rich conditions to yield fixed nitrogen species such as NH, HCN, H<sub>2</sub>CN, and CN. These, in turn, can be oxidized to NO in the lean zone of the flame. In most flames, especially those from nitrogen-containing fuels, the prompt mechanism is responsible for only a small fraction of the total NO<sub>x</sub>. Its control is important only when attempting to reach the lowest possible emissions.

**NO<sub>x</sub> emission control** It is preferable to minimize NO<sub>x</sub> formation through control of the mixing, combustion, and heat-transfer processes rather than through postcombustion techniques such as selective catalytic reduction. Four techniques for doing so, illustrated in Fig. 24-13, are air staging, fuel staging, flue-gas recirculation, and lean premixing.

**Air staging** Staging the introduction of combustion air can control NO<sub>x</sub> emissions from all fuel types. The combustion air stream is split to create a fuel-rich primary zone and a fuel-lean secondary zone. The rich primary zone converts fuel-bound nitrogen to molecular nitrogen and suppresses thermal NO<sub>x</sub>. Heat is removed prior to addition of the secondary combustion air. The resulting lower flame temperatures (below 1810 K [2800°F]) under lean conditions reduce the rate of formation of thermal NO<sub>x</sub>. This technique has been widely applied to furnaces and boilers and it is the preferred approach for burning liquid and solid fuels. Staged-air burners are typically capable of reducing NO<sub>x</sub> emissions by 30 to 60 percent, relative to uncontrolled levels. Air staging can also be accomplished by use of overfire air systems in boilers.

**Fuel staging** Staging the introduction of fuel is an effective approach for controlling NO<sub>x</sub> emissions when burning gaseous fuels. The first combustion stage is very lean, resulting in low thermal and prompt NO<sub>x</sub>. Heat is removed prior to injection of the secondary fuel. The secondary fuel entrains flue gas prior to reacting, further reducing flame temperatures. In addition, NO<sub>x</sub> reduction through reburning

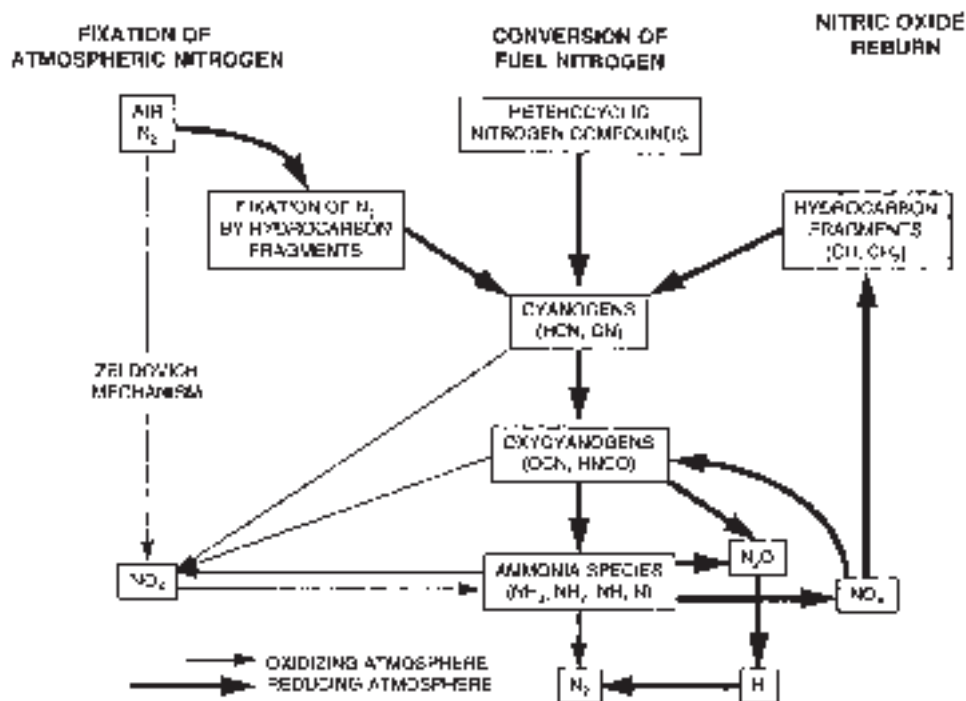

FIG. 24-12 Nitrogen oxide formation pathways in combustion.

reactions may occur in the staged jets. This technique is the favored approach for refinery- and chemical plant-fired heaters utilizing gaseous fuels. Staged-fuel burners are typically capable of reducing NO<sub>x</sub> emissions by 40 to 70 percent, relative to uncontrolled levels.

**Flue gas recirculation** Flue gas recirculation, alone or in combination with other modifications, can significantly reduce thermal NO<sub>x</sub>. Recirculated flue gas is a diluent that reduces flame temperatures. External and internal recirculation paths have been applied: internal recirculation can be accomplished by jet entrainment using either combustion air or fuel jet energy; external recirculation requires a fan or a jet pump (driven by the combustion air). When combined with staged-air or staged-fuel methods, NO<sub>x</sub> emissions from gas-fired burners can be reduced by 50 to 90 percent. In some applications, external flue-gas recirculation can decrease thermal efficiency. Condensation in the recirculation loop can cause operating problems and increase maintenance requirements.

**Lean premixing** Very low NO<sub>x</sub> emissions can be achieved by pre-mixing gaseous fuels (or vaporized liquid fuels) with air and reacting at high excess air. The uniform and very lean conditions in such systems favor very low thermal and prompt NO<sub>x</sub>. However, achieving such low emissions requires operating near the lean stability limit. This is an attractive NO<sub>x</sub> control approach for gas turbines, where operation at high excess air does not incur an efficiency penalty. In this application, NO<sub>x</sub> emissions have been reduced by 75 to 95 percent.

**Sulfur Oxides** Sulfur occurs in fuels as inorganic minerals (primarily pyrite, FeS<sub>2</sub>), organic structures, sulfate salts, and elemental sulfur. Sulfur contents range from parts per million in pipeline natural gas, to a few tenths of a percent in diesel and light fuel oils, to 0.5 to 5 percent in heavy fuel oils and coals. Sulfur compounds are pyrolyzed during the volatilization phase of oil and coal combustion and react in the gas phase to form predominantly SO<sub>2</sub> and some SO<sub>3</sub>. Conversion of fuel sulfur to these oxides is generally high (85 to 90 percent) and is relatively independent of combustion conditions. From 1 to 4 percent of the SO<sub>2</sub> is further oxidized to SO<sub>3</sub>, which is highly reactive and extremely hygroscopic. It combines with water to form sulfuric acid

aerosol, which can increase the visibility of stack plumes. It also elevates the dew point of water so that, to avoid back-end condensation and resulting corrosion, the flue-gas discharge temperature must be raised to about 420 K (300°F), reducing heat recovery and thermal efficiency. This reaction is enhanced by the presence of fine particles, which serve as condensation nuclei. Some coals may contain ash with substantial alkali content. In combustion of these fuels, the alkali may react to form condensed phase compounds (such as sulfates), thereby reducing the amount of sulfur emitted as oxides. Reductions in SO<sub>2</sub> emissions may be achieved either by removing sulfur from the fuel before and/or during combustion, or by postcombustion flue-gas desulfurization (wet scrubbing using limestone slurry, for example).

**Particulates** Combustion-related particulate emissions may consist of one or more of the following types, depending on the fuel.

**Mineral matter** derived from ash constituents of liquid and solid fuels can vaporize and condense as sub-micron-size aerosols. Larger mineral matter fragments are formed from mineral inclusions which melt and resolidify downstream.

**Sulfate particles** formed in the gas phase can condense. In addition, sulfate can become bound to metals and can be adsorbed on unburned carbon particles.

**Unburned carbon** includes unburned char, coke, cenospheres, and soot.

Particles of char are produced as a normal intermediate product in the combustion of solid fuels. Following initial particle heating and devolatilization, the remaining solid particle is termed *char*. Char oxidation requires considerably longer periods (ranging from 30 ms to over 1 s, depending on particle size and temperature) than the other phases of solid fuel combustion. The fraction of char remaining after the combustion zone depends on the combustion conditions as well as the char reactivity.

**Cenospheres** are formed during heavy oil combustion. In the early stages of combustion, the oil particle is rapidly heated and evolves volatile species, which react in the gas phase. Toward the end of the volatile-loss phase, the generation of gas declines rapidly and the

FIG. 24-13 Combustion modifications for  $\text{NO}_x$  control.

droplet (at this point, a highly viscous mass) solidifies into a porous coke particle known as a *cenosphere*. This is called *initial coke*. For the heaviest oils, the initial coke particle diameter may be 20 percent larger than the initial droplet diameter. For lighter residual oils, it may be only one third of the original droplet diameter. After a short interval, the initial coke undergoes contraction to form *final coke*. Final coke diameter is ~80 percent of the initial droplet diameter for the heaviest oils. At this time the temperature of the particle is approximately 1070 to 1270 K (1470 to 1830°F). Following coke formation, the coke particles burn out in the lean zone, but the heterogeneous oxidation proceeds slowly. Final unburned carbon levels depend on a balance between the amount of coke formed and the fraction burned out. Coke formation tends to correlate with fuel properties such as asphaltene content, C:H ratio, or Conradson Carbon Residue. Coke burnout depends on combustion conditions and coke reactivity. Coke reactivity is influenced by the presence of combustion catalysts (e.g., vanadium) in the cenospheres.

Formation of *soot* is a gas-phase phenomenon that occurs in hot, fuel-rich zones. Soot occurs as fine particles (0.02 to 0.2  $\mu\text{m}$ ), often agglomerated into filaments or chains which can be several millimeters long. Factors that increase soot formation rates include high C:H ratio, high temperature, very rich conditions, and long residence times at these conditions. Pyrolysis of fuel molecules leads to soot precursors such as acetylene and higher analogs and various polyaromatic hydrocarbons. These condense to form very small (< 2 nm) particles. The bulk of solid-phase material is generated by *surface growth*—attachment of gas-phase species to the surface of the particles and their incorporation into the particulate phase. Another growth mechanism is *coagulation*, in which particles collide and coalesce. Soot particle formation and growth

is typically followed by soot oxidation to form CO and  $\text{CO}_2$ . Eventual soot emission from a flame depends on the relative balance between the soot-formation and oxidation reactions.

**Carbon Monoxide** Carbon monoxide is a key intermediate in the oxidation of all hydrocarbons. In a well-adjusted combustion system, essentially all the CO is oxidized to  $\text{CO}_2$  and final emission of CO is very low indeed (a few parts per million). However, in systems which have low temperature zones (for example, where a flame impinges on a wall or a furnace load) or which are in poor adjustment (for example, an individual burner fuel-air ratio out of balance in a multiburner installation or a misdirected fuel jet which allows fuel to bypass the main flame), CO emissions can be significant. The primary method of CO control is good combustion system design and practice.

**Unburned Hydrocarbons** Various unburned hydrocarbon species may be emitted from hydrocarbon flames. In general, there are two classes of unburned hydrocarbons: (1) small molecules that are the intermediate products of combustion (for example, formaldehyde) and (2) larger molecules that are formed by pyro-synthesis in hot, fuel-rich zones within flames, e.g., benzene, toluene, xylene, and various polycyclic aromatic hydrocarbons (PAHs). Many of these species are listed as Hazardous Air Pollutants (HAPs) in Title III of the Clean Air Act Amendment of 1990 and are therefore of particular concern. In a well-adjusted combustion system, emission of HAPs is extremely low (typically, parts per trillion to parts per billion). However, emission of certain HAPs may be of concern in poorly designed or maladjusted systems.

## COMBUSTION OF SOLID FUELS

There are three basic modes of burning solid fuels, each identified with a furnace design specific for that mode: in suspension, in a bed at rest\* on a grate (fuel-bed firing), or in a fluidized bed. Although many variations of these generic modes and furnace designs have been devised, the fundamental characteristics of equipment and procedure remain intact. They will be described briefly.

**Suspension Firing** Suspension firing of pulverized coal (PC) is commoner than fuel-bed or fluidized-bed firing of coarse coal in the United States. This mode of firing affords higher steam-generation capacity, is independent of the caking characteristics of the coal, and responds quickly to load changes. Pulverized coal firing accounts for approximately 55 percent of the power generated by electric utilities in the United States. It is rarely used on boilers of less than 45.4 Mg/h (100,000 lb/h) steam capacity because its economic advantage decreases with size.

A simplified model of PC combustion includes the following sequence of events: (1) on entering the furnace, a PC particle is heated rapidly, driving off the volatile components and leaving a char particle; (2) the volatile components burn independently of the coal particle; and (3) on completion of volatiles combustion, the remaining char particle burns. While this simple sequence may be generally correct, PC combustion is an extremely complex process involving many interrelated physical and chemical processes.

**Devolatilization** The volatiles produced during rapid heating of coal can include  $\text{H}_2$ ,  $\text{CH}_4$ , CO,  $\text{CO}_2$ , and  $\text{C}_2$ - $\text{C}_4$  hydrocarbons, as well as tars, other organic compounds, and reduced sulfur and nitrogen species. The yield of these various fractions is a function of both heating rate and final particle temperature. The resulting char particle may be larger in diameter than the parent coal particle, owing to swelling produced by volatiles ejection. The particle density also decreases.

**Char oxidation** dominates the time required for complete burnout of a coal particle. The heterogeneous reactions responsible for char oxidation are much slower than the devolatilization process and gas-phase reaction of the volatiles. Char burnout may require from 30 ms to over 1 s, depending on combustion conditions (oxygen level, temperature), and char particle size and reactivity. Char reactivity depends on parent coal type. The rate-limiting step in char burnout can be chemical reaction or gaseous diffusion. At low temperatures or for very large particles, chemical reaction is the rate-limiting step. At

\*The burning fuel bed may be moved slowly through the furnace by the vibrating action of the grate or by being carried on a traveling grate.

higher temperatures boundary-layer diffusion of reactants and products is the rate-limiting step.

**Pulverized-Coal Furnaces** In designing and sizing PC furnaces, particular attention must be given to the following fuel-ash properties:

- Ash fusion temperatures, including the spread between initial deformation temperature and fluid temperature
- Ratio of basic (calcium, sodium, potassium) to acidic (iron, silicon, aluminum) ash constituents, and specifically iron-to-calcium ratio
- Ash content
- Ash friability

These characteristics influence furnace plan area, furnace volume, and burning zone size required to maintain steam production capacity for a given fuel grade or quality.

Coal properties influence pulverizer capacity and the sizing of the air heater and other heat-recovery sections of a steam generator. Furnace size and heat-release rates are designed to control slagging characteristics. Consequently, heat-release rates in terms of the ratio of net heat input to plan area range from 4.4 MW/m<sup>2</sup> ( $1.4 \times 10^6$  Btu/[h·ft<sup>2</sup>]) for severely slagging coals to 6.6 MW/m<sup>2</sup> ( $2.1 \times 10^6$  Btu/[h·ft<sup>2</sup>]) for low-slugging fuels.

The various burner and furnace configurations for PC firing are shown schematically in Fig. 24-14. The U-shaped flame, designated as *fantail vertical firing* (Fig. 24-14a), was developed initially for pulverized coal before the advent of water-cooled furnace walls. Because a large percentage of the total combustion air is withheld from the fuel stream until it projects well down into the furnace, this type of firing is well suited for solid fuels that are difficult to ignite, such as those with less than 15 percent volatile matter. Although this configuration is no longer used in central-station power plants, it may find favor again if low-volatile chars from coal-conversion processes are used for steam generation or process heating.

Modern central stations use the other burner-furnace configurations shown in Fig. 24-14, in which the coal and air are mixed rapidly in and close to the burner. The primary air, used to transport the pulverized coal to the burner, comprises 10 to 20 percent of the total combustion air. The secondary air comprises the remainder of the total air and mixes in or near the burner with the primary air and coal. The velocity of the mixture leaving the burner must be high enough to prevent flashback in the primary air-coal piping. In practice, this velocity is maintained at about 31 m/s (100 ft/s).

In *tangential firing* (Fig. 24-14b), the burners are arranged in vertical banks at each corner of a square (or nearly square) furnace and directed toward an imaginary circle in the center of the furnace. This results in the formation of a large vortex with its axis on the vertical centerline. The burners consist of an arrangement of slots one above the other, admitting, through alternate slots, primary air-fuel mixture and secondary air. It is possible to tilt the burners upward or downward, the maximum inclination to the horizontal being 30°, enabling the operator to selectively utilize in-furnace heat-absorbing surfaces, especially the superheater.

The circular burner shown in Fig. 24-15 is widely used in horizontally fired furnaces and is capable of firing coal, oil, or gas in capacities as high as 174 GJ/h ( $1.65 \times 10^8$  Btu/h). In such burners the air is often swirled to create a zone of reverse flow immediately downstream of the burner centerline, which provides for combustion stability.

*Low-NO<sub>x</sub> burners* are designed to delay and control the mixing of coal and air in the main combustion zone. A typical low-NO<sub>x</sub> air-staged burner is illustrated in Fig. 24-16. This combustion approach can reduce NO<sub>x</sub> emissions from coal burning by 40 to 50 percent. Because of the reduced flame temperature and delayed mixing in a low-NO<sub>x</sub> burner, unburned carbon emissions may increase in some applications and for some coals. *Overfire air* is another technique for

**FIG. 24-14** Burner and furnace configurations for pulverized-coal firing: (a) vertical firing; (b) tangential firing; (c) horizontal firing; (d) cyclone firing; (e) opposed-inclined firing.

FIG. 24-15 Circular burner for pulverized coal, oil, or gas. (From Marks' Standard Handbook for Mechanical Engineers, 8th ed., McGraw-Hill, New York, 1978.)

staging the combustion air to control NO<sub>x</sub> emissions when burning coal in suspension-firing systems. Overfire air ports are installed above the top level of burners on wall- and tangential-fired boilers. Use of overfire air can reduce NO<sub>x</sub> emissions by 20 to 30 percent. *Reburn* is a NO<sub>x</sub> control strategy that involves diverting a portion of the fuel from the burners to a second combustion zone (reburn zone) above the main burners. Completion air is added above the reburn zone to complete fuel burnout. The reburn fuel can be natural gas, oil, or pulverized coal, though natural gas is used in most applications. In this approach, the stoichiometry in the reburn zone is controlled to be slightly rich (equivalence ratio of ~1.15), under which conditions a portion (50 to 60 percent) of the NO<sub>x</sub> is converted to molecular nitrogen.

**Pulverizers** The pulverizer is the heart of any solid-fuel suspension-firing system. Air is used to dry the coal, transport it through the pulverizer, classify it, and transport it to the burner, where the transport air provides part of the air for combustion. The pulverizers themselves are classified according to whether they are under positive or negative pressure and whether they operate at slow, medium, or high speed.

Pulverization occurs by impact, attrition, or crushing. The capacity of a pulverizer depends on the grindability of the coal and the fineness desired, as shown by Fig. 24-17. Capacity can also be seriously reduced by excessive moisture in the coal, but it can be restored by

FIG. 24-17 Variation of pulverizer capacity with the grindability of the coal and the fineness to which the coal is ground. (Babcock & Wilcox Co.)

increasing the temperature of the primary air. Figure 24-18 indicates the temperatures needed. For PC boilers, the coal size usually is 65 to 80 percent through a 200-mesh screen, which is equivalent to 74 μm.

**Cyclone Furnaces** In *cyclone firing* (Fig. 24-14d) the coal is not pulverized but is crushed to 4-mesh (4.76-mm) size and admitted tangentially with primary air to a horizontal cylindrical chamber, called a *cyclone furnace*, which is connected peripherally to a boiler furnace. Secondary air also is admitted, so that almost all of the coal burns within the chamber. The combustion gas then flows into the boiler furnace. In the cyclone furnace, finer coal particles burn in suspension and the

**FIG. 24-18** Effect of moisture in coal on pulverizer capacity. Sufficient drying can be accomplished to restore capacity if air temperatures are high enough. [K = (°F + 459.7)/1.8] (Combustion Engineer, *Combustion Engineering Inc.*, New York, 1966.)

coarser ones are thrown centrifugally to the chamber wall, where most of them are captured in a sticky wall coating of molten slag. The secondary air, admitted tangentially along the top of the cyclone furnace, sweeps the slag-captured particles and completes their combustion. A typical firing rate is about 18.6 GJ/(h·m<sup>3</sup>) (500,000 Btu/[h·ft<sup>3</sup>]). The slag drains continuously into the boiler furnace and thence into a quenching tank. Figure 24-19 shows a cyclone furnace schematically.

**Fuel-Bed Firing** Fuel-bed firing is accomplished with mechanical stokers, which are designed to achieve continuous or intermittent fuel feed, fuel ignition, proper distribution of the combustion air, free release of the gaseous combustion products, and continuous or intermittent disposal of the unburned residue. These aims are met with two classes of stokers, distinguished by the direction of fuel feed to the bed: underfeed and overfeed. Overfeed stokers are represented by two types, distinguished by the relative directions of fuel and air flow (and also by the manner of fuel feed): crossfeed, also termed mass-burning, and spreader. The principles of these three methods of fuel-bed firing are illustrated schematically in Fig. 24-20.

**Underfeed Firing** Both fuel and air have the same relative direction in the underfeed stoker, which is built in single-retort and multiple-retort designs. In the *single-retort*, side-dump stoker, a ram pushes coal into the retort toward the end of the stoker and upward toward the tuyere blocks, where air is admitted to the bed. This type of stoker will handle most bituminous coals and anthracite, preferably in the size range 19 to 50 mm (¾ to 2 in) and no more than 50 percent through a 6-mm (¼-in) screen. Overfire air or steam jets are frequently used in the bridgewall at the end of the stoker to promote turbulence.

**FIG. 24-19** Cyclone furnace. (From Marks' Standard Handbook for Mechanical Engineers, 9th ed., McGraw-Hill, New York, 1987.)

**FIG. 24-20** Basic types of mechanical stokers: (a) underfeed; (b) crossfeed; (c) overfeed (spreader stoker).

In the *multiple-retort stoker*, rams feed coal to the top of sloping grates between banks of tuyeres. Auxiliary small sloping rams perform the same function as the pusher rods in the single retort. Air is admitted along the top of the banks of tuyeres, and on the largest units the tuyeres themselves are given a slight reciprocating action to agitate the bed further. This type of stoker operates best with caking coals having a relatively high ash-softening temperature. Coal sizing is up to 50 mm (2 in) with 30 to 50 percent through a 6-mm (¼-in) screen.

**Overfeed Firing: Crossfeed (Mass-Burning) Stokers** Cross-feed stokers are also termed mass-burning stokers because the fuel is dumped by gravity from a hopper onto one end of a moving grate, which carries it into the furnace and down its length. Because of this feature, crossfeed stokers are commonly called *traveling-grate* stokers. The grate may be either of two designs: *bar grate* or *chain grate*. Alternatively, the burning fuel bed may be conveyed by a vibratory motion of the stoker (*vibrating-grate*).

The fuel flows at right angles to the air flow. Only a small amount of air is fed at the front of the stoker, to keep the fuel mixture rich, but as the coal moves toward the middle of the furnace, the amount of air is increased, and most of the coal is burned by the time it gets halfway down the length of the grate. Fuel-bed depth varies from 100 to 200 mm (4 to 8 in), depending on the fuel, which can be coke breeze, anthracite, or any noncaking bituminous coal.

**Overfeed Firing: Spreader Stokers** Spreader stokers burn coal (or other fuel) by propelling it into the furnace. A portion of the coal burns in suspension (the percentage depending on the coal fineness), while the rest burns on a grate. In most units, coal is pushed off a plate under the storage hopper onto revolving paddles (either overthrow or underthrow) which distribute the coal on the grate (Fig. 24-20c). The angle and speed of the paddles control coal distribution. The largest coal particles travel the farthest, while the smallest ones become partially consumed during their trajectory and fall on the forward half of the grate. The grate may be stationary or traveling. The fuel and air flow in opposite directions.

Some spreaders use air to transport the coal to the furnace and distribute it, while others use mechanical means to transport the coal to a series of pneumatic jets.

The performance of spreader stokers is affected by changes in coal sizing. The equipment can distribute a wide range of fuel sizes, but it distributes each particle on the basis of size and weight. Normal size specifications call for 19-mm (¾-in) nut and slack with not more than 30 percent less than 6.4 mm (¼ in).

Typically, approximately 30 to 50 percent of the coal is burned in suspension. If excessive fines are present, more coal particles will be

carried out of the furnace and burned in suspension, and very little ash will be available to provide a protective cover for the grate surface. On the other hand, if sufficient fines are not present, not all the fuel will be burned on the grate, resulting in derating of the unit and excessive dumping of live coals to the ash hopper.

Excess air is usually 30 to 40 percent for stationary and dumping grates, while traveling grates are operated with from 22 to 30 percent excess air. Preheated air can be supplied for all types of grates but the temperature is usually limited to 395 to 422 K (250 to 300°F) to prevent excessive slagging of the fuel bed.

Overfire air nozzles are located in the front wall underneath the spreaders and in the rear wall from 0.3 to 0.9 m (1 to 3 ft) above the grate level. These nozzles use air directly from a fan or inspirate air with steam to provide turbulence above the grate for most effective mixing of fuel and air. They supply about 15 percent of the total combustion air.

**Comparison of Suspension and Fuel-Bed Firing** A major factor to consider when comparing a stoker-fired boiler with a PC boiler is the reduction in efficiency due to carbon loss. The carbon content of the ash passing out of a spreader stoker furnace varies from 30 to 50 percent. Overall efficiency of the stoker can be increased by reburning the ash: it is returned to the stoker grate by gravity or a pneumatic feed system. A continuous-ash-discharge spreader-stoker-fired unit will typically have a carbon loss of 4 to 8 percent, depending on the amount of ash reinjection. A properly designed PC boiler, on the other hand, can maintain an efficiency loss due to unburned carbon of less than 0.4 percent.

A difference between these firing methods may also be manifested in the initial fuel cost. For efficient operation of a spreader-stoker-fired boiler, the coal must consist of a proper mixture of coarse and fine particles. Normally, double-screened coal is purchased because less expensive run-of-mine coal does not provide the optimum balance of coarse and fine material.

An advantage of a stoker-fired furnace is its easy adaptability to firing almost any unsized solid fuels. Bark, bagasse, or refuse can normally be fired on a stoker to supplement the coal with a minimum amount of additional equipment. Thus, such supplementary waste fuels may be able to contribute a higher percentage of the total heat input in a stoker-fired furnace than in a PC furnace without expensive equipment modifications.

**Fluidized-Bed Combustion** The principles of gas-solid fluidization and their application to the chemical process industry are treated in Sec. 17. Their general application to combustion is reviewed briefly here, and their more specific application to fluidized-bed boilers is discussed later in this section.

In fluidized-bed combustion (FBC), fuel is burned in a bed of particles supported in an agitated state by an upward flow of air introduced via an air distributor. The bed particles may be sand or ash derived from the fuel, or spent sorbent (limestone or dolomite) if in-bed sulfur capture is included in the design. The fluidizing action promotes good solids mixing and gas-solids contacting that allow high combustion efficiency to be achieved at temperatures significantly lower than those of a pulverized coal (PC) furnace (typically 1116 K [1550°F] compared to over 1589 K [2400°F]). These lower temperatures also result in reduced slagging and fouling problems and significantly lower NO<sub>x</sub> formation. This latter benefit, in conjunction with in-bed sulfur capture capability, constitutes one of the great advantages of fluidized-bed combustion: in situ pollution control. Having this control built into the furnace reduces the extent of back-end clean up required for a given emissions standard.

There are two types of FBC unit being sold commercially, *bubbling* and *circulating*, both operating at atmospheric pressure. Typical superficial fluidizing velocities are as follows.

Bubbling FBC 1.5 to 2.7 m/s (5 to 9 ft/s)

Circulating FBC 3.7 to 7.3 m/s (12 to 24 ft/s)

Pressurized FBC (PFBC) designs, bubbling and circulating, have been under development since the 1970s, but all work has now been curtailed. Work on an advanced PFBC design, incorporating partial coal gasification and char combustion, has also been curtailed. Several commercial bubbling PFBC units were built in the 1990s, covering the range 80 to 340 MWe. However, no new PFBC plants have been

announced since 1996, and consequently the technology is dropped from this edition of the Handbook.

**Bubbling Beds** A large proportion of the noncombustible feedstock—sand, ash, or sorbent-derived material—remains in the combustor forming the bed. Bed depth is maintained by draining off excess material. Most of the gas in excess of that required for minimum fluidization appears as bubbles (voids), and these carry particles upward in their wake, resulting in the rapid vertical mixing of the bed material that promotes even temperatures and good gas-solids contacting.

Early bubbling FBC units were designed to burn coal, and the heat released was removed by heat transfer to in-bed tubes and/or to the water-wall tubes used to enclose the furnace. These surfaces experienced high rates of metal loss through the combined effects of erosion and abrasion. Protective measures such as plasma-sprayed coatings and metal fins to disrupt the solids flow pattern were used. These were effective for only short periods before requiring replacement, and so maintenance requirements were high.

The two largest bubbling-bed FBC units built, 160 and 350 MWe, entered into service in the late 1980s burning bituminous coal. However, for coal applications, the overall performance of circulating fluidized-bed units has proved superior, and bubbling-bed designs of this size are no longer marketed. The bubbling technology is now mainly used for burning high-moisture biomass fuels for which in-bed heat-transfer surfaces are not required. These units are usually designed for generating capacities below 120 MWe, and typical fuels include wood wastes, paper mill and sewage sludges, and peat.

The boilers are of water-wall construction with the walls in the bed region lined with refractory to protect against erosion and abrasion damage. The heat released in the bed is removed from the flue gas by the exposed water walls and by convection pass tubing set in the gas path after the boiler. The coal boilers included multiclones to collect elutriated carbon and recycle it back to the boiler to increase combustion efficiency. However, because biomass is more reactive, recycle is not required.

To accommodate the wide variations in fuel moisture content while maintaining close bed temperature control, two control strategies are used.

- Operate the bed substoichiometrically so that bed temperature varies with the fluidizing air (primary combustion air). There is an equal and opposite change in the air fed above the bed (secondary combustion air) to complete the combustion process, the total air remaining constant. As the fuel moisture increases, the primary airflow rate increases, increasing the fluidizing velocity and releasing more heat in the bed to evaporate the additional water and keep the bed temperature constant. The bed operates less substoichiometrically, and in-bed combustion efficiency increases. At the same time the secondary air is reduced, and as there is less above-bed combustion, the upper furnace temperature falls. The control action is reversed when the fuel moisture content decreases. The split of primary to secondary airflow ranges from above 80:20 for high-moisture fuels to below 50:50 for low-moisture fuels.
- The above strategy results in variations in fluidizing velocity that might produce poor fluidization at some operating conditions with a resulting reduction in combustion efficiency. To maintain fluidizing velocity constant, recirculated flue gas is mixed with the primary combustion air to lower its oxygen content while keeping the combined fluidization gas flow rate constant. Air may be fed above the bed to complete combustion, but this is controlled independently of the air passing to the bed. As the fuel moisture increases, less flue gas is recirculated, the oxygen content of the primary combustion air and in-bed combustion both increase, and secondary air decreases. The control action is reversed when the fuel moisture content decreases.

**Circulating Beds** These fluidized beds operate at higher velocities, and virtually all the solids are elutriated from the furnace. The majority of the elutriated solids, still at combustion temperature, are captured by reverse-flow cyclone(s) and recirculated to the foot of the combustor. The foot of the combustor is a potentially very erosive region, as it contains large particles not elutriated from the bed, and they are being fluidized at high velocity. Consequently, the lower reaches of the combustor do not contain heat-transfer tubes and the water walls are protected with refractory. Some combustors have

experienced damage at the interface between the water walls and the refractory, and measures similar to those employed in bubbling beds have been used to protect the tubes in this region.

The circulating-bed design is the leading FBC technology and is the only design currently offered at sizes above 120 MWe. Units as large as 320 MWe have been built incorporating subcritical steam conditions with reheat and supercritical designs of up to 600 MWe are available. The fuels used in these designs are coals or opportunity fuels such as petroleum coke, although one 240-MWe unit is designed to operate solely on biomass. Circulating FBC boilers as small as 25 MWe have been built to fire either coal or biomass. However, as the size gets smaller, the circulating FBC becomes less competitive for biomass firing, and as indicated earlier, the bubbling FBC design is favored for this application.

The heat released in the furnace is removed from the flue gas by the exposed upper water-wall tubes. As the units increase in size, more heat-transfer surface is required than is provided by the walls. Surface can be added by wrapping horizontal tubing over the walls of the upper furnace, or by added wing walls, sections of water wall extending short distances into the furnace enclosure. In some designs, tubes are extended across the upper furnace where, although the fluidizing velocity is still high, the erosion potential is low because the solids are finer and their concentration is lower. In some designs, heat is removed from the recirculated solids by passing them through a bubbling-bed heat exchanger before returning them to the furnace. The potential for erosion or abrasion of the tubes in this bed is low as the recirculating solids are mostly less than 500  $\mu\text{m}$  and are well fluidized at velocities of only around 0.6 m/s [2 ft/s].

The combustion air is introduced at two levels, 60 to 70 percent being introduced through the distributor and 30 to 40 percent above the bed. This staged entry results in the lower reaches operating substoichiometrically, which helps to reduce  $\text{NO}_x$  emissions but tends to reduce the fluidizing velocity at the base of the combustor. To compensate for this and to increase solids mixing by increasing the local gas velocity, the portion of the combustor below the secondary air entry points is tapered.

**Fuel Flexibility** An advantage of FBC designs is fuel flexibility: a single unit can burn a wider range of fuels than a PC furnace, thus offering owners an improved bargaining position to negotiate lower fuel prices. Among the fuels fired are bituminous and subbituminous coals, anthracite culm, lignite, petroleum coke, refuse-derived fuel, biomass, industrial and sewage sludges, and shredded tires. But fuel flexibility can be achieved only if the unit is designed for the range of fuels intended to be burned. For example, to maintain the same firing rate, a feed system designed for a certain fuel must be capable of feeding a lower calorific fuel at a higher rate. Similarly, to maintain the same degree of sulfur capture, feeders must be capable of delivering sorbent over a range of rates matching the sulfur contents of the fuels likely to be fed. This increase in operating flexibility increases the capital cost, offsetting at least partially the economic benefits of reduced fuel pricing.

**Sulfur Emissions** Sulfur present in a fuel is released as  $\text{SO}_2$ , a known contributor to acid rain deposition. By adding limestone or dolomite to a fluidized bed, much of this can be captured as calcium sulfate, a dry nonhazardous solid. As limestone usually contains over 40 percent calcium, compared to only 20 percent in dolomite, it is the preferred sorbent, resulting in lower transportation costs for the raw mineral and the resulting ash product. Moreover, the high magnesium content of the dolomite makes the ash unsuitable for some building applications and so reduces its potential for utilization. Whatever sorbent is selected, for economic reasons it is usually from a source local to the FBC plant. If more than one sorbent is available, plant trials are needed to determine the one most suitable, as results from laboratory-scale reactivity assessments are unreliable.

At atmospheric pressure, calcium carbonate almost completely calcines to free lime, and it is this that captures the sulfur dioxide. As the free lime is not completely sulfated, the resulting sorbent ash is very alkaline, consisting primarily of  $\text{CaSO}_4$  and  $\text{CaO}$ , with small amounts of  $\text{CaCO}_3$ .

The sulfation reaction has an optimum at a mean bed temperature of around 1116 K (1550°F). Units are usually designed to operate at this

temperature, but changes in operating conditions to achieve power output and accommodate changes in fuel composition often result in the plant operating at above or below the optimum temperature. To compensate for the ensuing reduction in sulfur capture, more sorbent is fed to the bed.

Emissions standards are becoming increasingly more stringent, and environmental permits for recent CFB projects have required sulfur capture efficiencies greater than 98 percent. Achieving this with only in-bed sulfur capture requires Ca/S molar ratios as high as 3 (3 mol of calcium in the sorbent for each mole of sulfur in the coal). For a 3 percent sulfur coal and a sorbent with 38 percent calcium, the sorbent-to-coal weight ratio is 0.3. To reduce the sorbent demand for the same sulfur capture efficiency, a back-end dry scrubber is used to remove additional  $\text{SO}_2$  from the flue gas. This has been demonstrated to lower the Ca/S molar ratio to 1.9, a sorbent-to-coal weight ratio of 0.19. For a coal with 12 percent ash, this 37 percent reduction in sorbent feed rate reduces the amount of ash sent to disposal by 17 percent. This reduction in solids handling requirements improves process economics primarily by lowering the operating costs of the plant. The capital cost remains roughly the same, the cost of the dry scrubber being mainly offset by the reduction in solids handling equipment.

The sorbent used in the dry scrubber can be either lime or reactivated ash captured by the baghouse. The baghouse ash contains unreacted sorbent particles with a surface coating of calcium sulfate that prevents  $\text{SO}_2$  reaching the  $\text{CaO}$  at their core. Hydrating these solids causes the material to swell and crack, thus exposing the unreacted  $\text{CaO}$ , which when recycled back to the boiler is available to react with additional  $\text{SO}_2$ . As lime is more expensive than limestone, using the baghouse ash is the preferred approach. It also eliminates the need to provide separate handling facilities for lime.

**Nitrogen Oxide Emissions** FBC units achieve excellent combustion and sulfur emission performance at relatively modest combustion temperatures in the range of 1060 to 1172 K [1450 to 1650°F]. At these temperatures no atmospheric nitrogen is converted to  $\text{NO}_x$ . The prime variables influencing  $\text{NO}_x$  formation are excess air, mean bed temperature, nitrogen content of the fuel, and Ca/S molar ratio. With respect to the latter, high sorbent feed rates increase the free lime content, and this catalyzes  $\text{NO}_2$  formation. Typical  $\text{NO}_x$  emissions, consisting of around 90 percent  $\text{NO}$  and 10 percent  $\text{NO}_2$ , are in the range 86 to 129 mg/MJ [0.2 to 0.3 lb/MBtu]. These values have been reduced to as low as 21 mg/MJ [0.05 lb/MBtu] by injecting ammonia into the boiler freeboard to promote selective noncatalytic reduction (SNCR) reactions. This is a less costly approach than the selective catalytic reduction (SCR) units required for PC plants.

Because the operating temperature is lower, FBC units release more  $\text{N}_2\text{O}$  than do PC units. Nitrous oxide is a greenhouse gas that absorbs 270 times more heat per molecule than carbon dioxide and as such is likely to come under increased scrutiny in the future. The emissions at full load from coal-fired units are around 65 mg/MJ [0.15 lb/MBtu], but these increase as load is reduced and furnace temperature falls. Measurements from biomass-fired FBCs have not been made. Combustion processes do not contribute greatly to current U.S.  $\text{N}_2\text{O}$  emissions; agriculture and motor vehicles account for 86 percent of the total.

**Particulate Emissions** To meet environmental regulations, FBC boilers use a back-end particulate collector, such as a baghouse or an electrostatic precipitator (ESP). Compared to PC units, because of its sulfur sorbent content, the ash from a circulating CFB has higher resistivity and is finer because the flue gas path contains cyclones. Both factors result in a reduction in ESP collection efficiency, although lowering the gas velocity and providing additional collection fields can compensate for this albeit at increased capital cost. Bubbling FBC designs fired on biomass do not normally feed sulfur sorbents and do not include dust collectors in the flue gas path. For these applications suitably designed ESPs are often included. In general, however, baghouses are the preferred particulate collection devices.

FBC ash is irregular, whereas PC ash, because it melts at the elevated operating temperatures, is spherical. This difference in shape influences baghouse design in three ways: (1) FBC ash does not flow from the collection hoppers as readily and special attention has to be given to their design; (2) FBC ash forms a stronger cake, requiring more frequent and more robust cleaning mechanisms, e.g., shake-deflate and

pulse-jet technologies; and (3) this more robust action in conjunction with the more abrasive, irregular particles results in filter bags being more prone to failure in FBC systems. Careful selection of bag materials (synthetic felts generally perform best) and good installation and maintenance practices minimize the latter problem.

**Mercury Emissions** The U.S. Environmental Protection Agency (EPA) has proposed new rules that require power plants to reduce their mercury emissions by 70 percent by 2018. Tests on operating fluidized beds show that inherent mercury capture from the flue gas for bituminous coals is over 90 percent, but for lignites capture is closer to 50 percent. The reasons for this difference are not fully understood but could be explained by the higher reactivity of lignite resulting in lower unburned carbon carryover. Carbon is known to adsorb elemental and ionic mercury, and a low carbon content will result in reduced mercury capture. The combustion efficiency for less reactive bituminous coal is lower, resulting in more carbon carryover and possibly accounting for the higher mercury capture. Recent tests have shown that halide-impregnated activated carbons injected into flue gas streams can capture over 90 percent of the mercury present. So the low inherent mercury capture associated with lignite can be compensated for by activated carbon injection ahead of the dust collection device used.

**COMBUSTION OF LIQUID FUELS**

Oil is typically burned as a suspension of droplets generated by atomizing the fuel. As the droplets pass from the atomizer into the flame zone, they are heated both by radiation from the flame and by convection from the hot gases that surround them, and the lighter fuel components vaporize. The vapors mix with surrounding air and ignite. Depending on the fuel type, the fuel droplet may be completely vaporized or it may be partially vaporized, leaving a residual char or coke particle.

Fuel oils can contain a significant amount of sulfur: in the case of high-sulfur No. 6, it may be as much as 4 percent (Table 24-6). SO<sub>2</sub> is the principal product of sulfur combustion with stoichiometric or leaner fuel-air mixtures, but with the excess air customarily used for satisfactory combustion, SO<sub>3</sub> can form and then condense as sulfuric acid at temperatures higher than the normally expected dew point. Thus air preheaters and other heat recovery equipment in the flue-gas stream can be endangered. Figure 24-21 shows the maximum safe upper limits for dew points in the stacks of furnaces burning sulfur-containing oil and emitting unscrubbed flue gas.

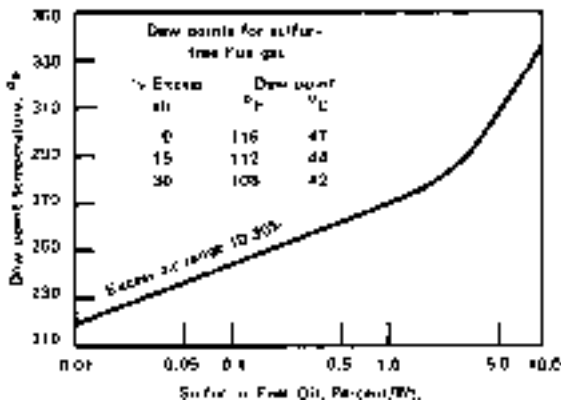

**Atomizers** Atomization is the process of breaking up a continuous liquid phase into discrete droplets. Figure 24-22 shows the idealized process by which the surface area of a liquid sheet is increased until it forms droplets. Atomizers may be classified into two broad groups (see Fig. 24-23), pressure atomizers, in which fuel oil is injected at high pressure, and twin-fluid atomizers, in which fuel oil is injected at moderate pressure and a compressible fluid

**FIG. 24-22** Idealized process of drop formation by breakup of a liquid sheet. (After Dombrowski and Johns, Chem. Eng. Sci. 18:203, 1963.)

(steam or air) assists in the atomization process. Low oil viscosity (less than 15 mm<sup>2</sup>/s) is required for effective atomization (i.e., small droplet size). Light oils, such as No. 2 fuel oil, may be atomized at ambient temperature. However, heavy oils must be heated to produce the desired viscosity. Required preheats vary from approximately 373 K (212°F) for No. 6 oil to 623 K (480°F) for vacuum bottoms.

**Pressure Atomizers** The commonest type of pressure atomizer is the swirl-type (Fig. 24-24). Entering a small cup through tangential orifices, the oil swirls at high velocity. The outlet forms a dam around the open end of the cup, and the oil spills over the dam in the form of a thin conical sheet, which subsequently breaks up into thin filaments and then droplets. Depending on the fuel viscosity, operating pressures range from 0.69 to 6.9 MPa (100 to 1000 psia) and the attainable

**FIG. 24-21** Maximum flue-gas dew point versus percent of sulfur in typical oil fuels. (K = [°F + 459.7]/1.8)

**FIG. 24-23a** Common types of atomizers: pressure atomizers. (From Lefebvre, Atomization and Sprays, Hemisphere, New York, 1989. Reproduced with permission. All rights reserved.)

FIG. 24-23b Common types of atomizers: twin-fluid atomizers. (From Lefebvre, *Atomization and Sprays*, Hemisphere, New York, 1989. Reproduced with permission. All rights reserved.)

turn-down ratio is approximately 4:1. Pressure atomization is most effective for lighter fuel oils.

**Twin-Fluid Atomizers** In a twin-fluid atomizer, the fuel stream is exposed to a stream of air or steam flowing at high velocity. In the internal-mixing configuration (Fig. 24-25), the liquid and gas mix inside the nozzle before discharging through the outlet orifice. In the external-mixing nozzle, the oil stream is impacted by the high-velocity gas stream outside the nozzle. The internal type requires lower flows of secondary fluid. In industrial combustion systems, steam is the preferred atomizing medium for these nozzles. In gas turbines, compressed air is more readily available. Maximum oil pressure is about 0.69 MPa (100 psia), with the steam or air pressure being maintained about 0.14 to 0.28 MPa (20 to 40 psia) in excess of the oil pressure. The mass flow of atomizing fluid varies from 5 to 30 percent of the fuel flow rate, and represents only a modest energy consumption. Turn-down performance is better than for pressure atomizers and may be as high as 20:1.

A well-designed atomizer will generate a cloud of droplets with a mean size of about 30 to 40  $\mu\text{m}$  and a top size of about 100  $\mu\text{m}$  for light oils such as No. 2 fuel oil. Mean and top sizes are somewhat larger than this for heavier fuel oils.

**Oil Burners** The structure of an oil flame is shown in Fig. 24-26, and Fig. 24-27 illustrates a conventional circular oil burner for use in boilers. A combination of stabilization techniques is used, typically including swirl. It is important to match the droplet trajectories to the combustion aerodynamics of a given burner to ensure stable ignition and good turn-down performance.

Many oil burners are designed as combination gas/oil burners. An example of a modern low- $\text{NO}_x$  oil/gas forced-draft burner is shown in Fig. 24-28. This is an air-staged design, with the air divided into primary, secondary, and tertiary streams. An air-staged natural draft process heater oil/gas burner is illustrated in Fig. 24-29.

Emissions of unburned carbon (primarily coke cenospheres) may be reduced by (1) achieving smaller average fuel droplet size (e.g., by heating the fuel to lower its viscosity or by optimizing the atomizer geometry), (2) increasing the combustion air preheat temperature, or (3) firing oils with high vanadium content (vanadium appears to catalyze the burnout of coke).

FIG. 24-24 Swirl pressure-jet atomizer. (From Lefebvre, *Atomization and Sprays*, Hemisphere, New York, 1989. Reproduced with permission. All rights reserved.)

**COMBUSTION OF GASEOUS FUELS**

Combustion of gas takes place in two ways, depending upon when gas and air are mixed. When gas and air are mixed before ignition, as in a Bunsen burner, burning proceeds by hydroxylation. The hydrocarbons and oxygen form hydroxylated compounds that become aldehydes; the addition of heat and additional oxygen breaks down the aldehydes to  $\text{H}_2$ ,  $\text{CO}$ ,  $\text{CO}_2$ , and  $\text{H}_2\text{O}$ . Inasmuch as carbon is converted to aldehydes in the initial stages of mixing, no soot can be developed even if the flame is quenched.

Cracking occurs when oxygen is added to hydrocarbons after they have been heated, decomposing the hydrocarbons into carbon and hydrogen, which, when combined with sufficient oxygen, form  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . Soot and carbon black are formed if insufficient oxygen is present or if the combustion process is arrested before completion.

**FIG. 24-26** Structure of typical oil flame. (From *Lawn, Principles of Combustion Engineering for Boilers*, Academic Press, London, 1987. Reprinted with permission.)

**Gas Burners** Gas burners may be classified as premixed or non-premixed. Many types of flame stabilizer are employed in gas burners. Bluff body, swirl, and combinations thereof are the predominant stabilization mechanisms.

**Fully Premixed Burners** A fully premixed burner includes a section for completely mixing the fuel and air upstream of the burner.

**FIG. 24-27** Circular register burner with water-cooled throat for oil firing. (Babcock & Wilcox Co.)

**FIG. 24-28** Low-NO<sub>x</sub> combination oil/gas forced-draft boiler burner. (Todd Combustion, Inc.)

The burner proper consists essentially of a flame holder. The porting that admits the mixture to the combustion chamber is designed to produce a fairly high velocity through a large number of orifices to avoid the possibility of the flame flashing back through the flame holder and igniting the mixture upstream of the burner.

Surface combustion devices are designed for fully premixing the gaseous fuel and air and burning it on a porous radiant surface. The close coupling of the combustion process with the burner surface results in low flame temperatures and, consequently, low NO<sub>x</sub> formation. Surface materials can include ceramic fibers, reticulated ceramics, and metal alloy mats. This approach allows the burner shape to be customized to match the heat transfer profile with the application.

**Partially Premixed Burners** These burners have a premixing section in which a mixture that is flammable but overall fuel-rich is generated. Secondary combustion air is then supplied around the flame holder. The fuel gas may be used to aspirate the combustion air or vice versa, the former being the commoner. Examples of both are provided in Figs. 24-30 and 24-31.

**Nozzle-Mix Burners** The most widely used industrial gas burners are of the nozzle-mix type. The air and fuel gas are separated until they are rapidly mixed and reacted after leaving the ports. These burners allow a wide range of fuel-air ratios, a wide variety of flame shapes, and multifuel firing capabilities. They can be used to generate special atmospheres by firing at very rich conditions (50 percent excess fuel) or very lean conditions (1000 percent excess air). By changing nozzle shape and degree of swirl, the flame profile and mixing rates can be varied widely, from a rapid-mixing short flame ( $L/D = 1$ ), to a conventional flame ( $L/D = 5$  to 10), to a slow-mixing long flame ( $L/D = 20$  to 50).

**Staged Burners** As was pointed out earlier under "Pollutant Formation and Control in Flames," the proper staging of fuel or air in the combustion process is one technique for minimizing NO<sub>x</sub> emissions. Gas burners that achieve such staging are available.

**Air-staged burners** Low-NO<sub>x</sub> air-staged burners for firing gas (or oil) are shown in Fig. 24-28. A high-performance, low-NO<sub>x</sub> burner for high-temperature furnaces is shown in Fig. 24-32. In this design, both air-staging and external flue-gas recirculation are used to achieve extremely low levels of NO<sub>x</sub> emissions (approximately 90 percent lower than conventional burners). The flue gas is recirculated by a jet-pump driven by the primary combustion air.

**Fuel-staged burners** Use of fuel-staged burners is the preferred combustion approach for NO<sub>x</sub> control because gaseous fuels typically contain little or no fixed nitrogen. Figure 24-33 illustrates a fuel-staged natural draft refinery process heater burner. The fuel is split into primary (30 to 40 percent) and secondary (60 to 70 percent) streams. Furnace gas may be internally recirculated by the primary gas jets for additional NO<sub>x</sub> control. NO<sub>x</sub> reductions of 80 to 90 percent have been achieved by staging fuel combustion.

## THERMAL ENERGY CONVERSION AND UTILIZATION

### BOILERS

Steam generators are designed to produce steam for process requirements, for process needs along with electric power generation, or solely for electric power generation. In each case, the goal is the most efficient and reliable boiler design for the least cost. Many factors influence the selection of the type of steam generator and its design, and some of these will be treated later in discussions of industrial and utility boilers.

Figure 24-34 shows the chief operating characteristics of a range of boilers, from small-scale heating systems to large-scale utility boilers.

In the industrial market, boilers have been designed to burn a wide range of fuels and operate at pressures up to 12.4 MPa (1800 psia) and steaming rates extending to 455,000 kg/h (1,000,000 lb/h). High-capacity shop-assembled boilers (package boilers) range in capacity from 4545 kg/h (10,000 lb/h) to about 270,000 kg/h (600,000 lb/h).

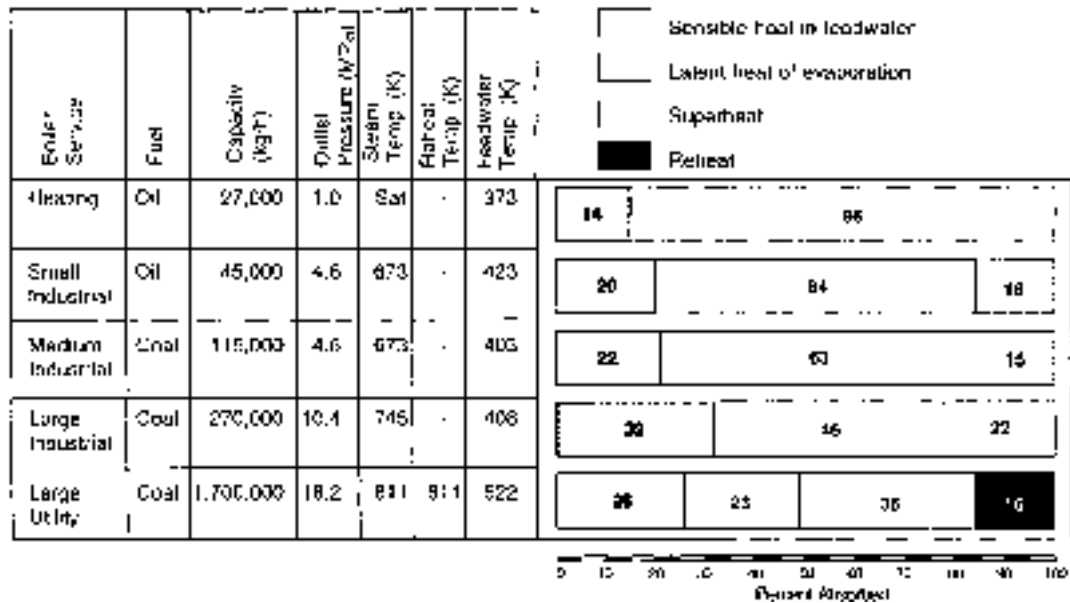

FIG. 24-34 Heat absorption distribution for various types of boilers. (Adapted from Singer, Combustion—Fossil Power, 4th ed., Combustion Engineering, Inc., Windsor, Conn., 1991.)

These units are designed for operation at pressures up to 11.4 MPa (1650 psia) and 783 K (950°F). Figure 24-35 shows a gas- or liquid-fuel-fired unit. While most shop-assembled boilers are gas- or oil-fired, designs are available to burn pulverized coal. A field-erected coal-fired industrial boiler is shown in Fig. 24-36.

Boilers designed for service in electric power utility systems operate at both subcritical-pressure (pressures below 22.1 MPa [3205 psia]) and supercritical-pressure steam conditions. Subcritical-pressure boilers range in design pressures up to about 18.6 MPa (2700 psia) and in steaming capacities up to about 2955 Mg/h (6,500,000 lb/h). Supercritical-pressure boilers have been designed to operate at pressures up to 34.5 MPa (5000 psia). The 24.1 MPa (3500 psia) cycle has been firmly established in the utility industry, and boilers with steaming capacities up to 4227 Mg/h (9,300,000 lb/h) and superheat and reheat temperatures of 814 K (1005°F) are in service. The furnace of a large coal-fired steam generator absorbs half of the heat released, so that the gas temperature leaving the furnace is about 1376 K (2000°F).

**Boiler Design Issues** Boiler design involves the interaction of many variables: water-steam circulation, fuel characteristics, firing systems and heat input, and heat transfer. The furnace enclosure is one of the most critical components of a steam generator and must be conservatively designed to assure high boiler availability. The furnace configuration and its size are determined by combustion requirements, fuel characteristics, emission standards for gaseous effluents and particulate matter, and the need to provide a uniform gas flow and temperature entering the convection zone to minimize ash deposits and excessive superheater metal temperatures. Discussion of some of these factors follows.

**Circulation and Heat Transfer** Circulation, as applied to a steam generator, is the movement of water or steam or a mixture of both through the heated tubes. The circulation objective is to absorb heat from the tube metal at a rate that assures sufficient cooling of the furnace-wall tubes during all operating conditions, with an adequate margin of reserve for transient upsets. Adequate circulation prevents excessive metal temperatures or temperature differentials that would cause failures due to overstressing, overheating, or corrosion.

The rate of heat transfer from the tubes to the fluid depends primarily on turbulence and the magnitude of the heat flux itself. Turbulence is a

FIG. 24-35 Shop-assembled radiant boiler for natural gas or oil. (Babcock & Wilcox Co.)

FIG. 24-36 Field-erected radiant boiler for pulverized coal. (Babcock & Wilcox Co.)

function of mass velocity of the fluid and tube roughness. Turbulence has been achieved by designing for high mass velocities, which ensure that nucleate boiling takes place at the inside surface of the tube. If sufficient turbulence is not provided, *departure from nucleate boiling* (DNB) occurs. DNB is the production of a film of steam on the tube surface that impedes heat transfer and results in tube overheating and possible failure.

Satisfactory performance is obtained with tubes having helical ribs on the inside surface, which generate a swirling flow. The resulting centrifugal action forces the water droplets toward the inner tube surface and prevents the formation of a steam film. The internally rifled tube maintains nucleate boiling at much higher steam temperature and pressure and with much lower mass velocities than those needed in smooth tubes. In modern practice, the most important criterion in drum boilers is the prevention of conditions that lead to DNB.

**Utility Steam Generators**

**Steam-Generator Circulation System** Circulation systems for utility application are generally classified as natural circulation and forced or pump-assisted circulation in drum-type boilers, and as once-through flow in subcritical- and supercritical-pressure boilers.

Natural circulation in a boiler circulation loop depends only on the difference between the mean density of the fluid (water) in the downcomers and the mean density of the fluid (steam-water mixture) in the heated furnace walls. The actual circulating head is the difference between the total gravity head in the downcomer and the integrated gravity heads in the upcoming legs of the loop containing the heated tubes. The circulating head must balance the

sum of the losses due to friction, shock, and acceleration throughout the loop.

In a once-through system, the feedwater entering the unit absorbs heat until it is completely converted to steam. The total mass flow through the waterwall tubes equals the feedwater flow and, during normal operation, the total steam flow. As only steam leaves the boiler, there is no need for a steam drum.

**Fuel Characteristics** Fuel choice has a major impact on boiler design and sizing. Because of the heat transfer resistance offered by ash deposits in the furnace chamber in a coal-fired boiler, the mean absorbed heat flux is lower than in gas- or oil-fired boilers, so a greater surface area must be provided.

In addition, coal characteristics have a major impact on the design and operation of a coal-fired boiler. Coals having a low volatile-matter content usually require higher ignition temperatures and those with less than 12 to 14 percent volatile matter may require supplementary fuel to stabilize ignition. Generally, western U.S. coals are more reactive than others and, consequently, easier to ignite, but because of high moisture content they require higher air temperatures to the mills for drying the coal to achieve proper pulverization. Extremely high-ash coal also may present problems in ignition and stabilization. The ash constituents and the quantity of ash will have a decided influence on sizing the furnace. Accordingly, a thorough review of coal characteristics is needed to establish the effect on the design and operation of a boiler.

**Superheaters and Reheaters** A superheater raises the temperature of the steam generated above the saturation level. An important function is to minimize moisture in the last stages of a turbine to avoid blade erosion. With continued increase of evaporation temperatures and pressures, however, a point is reached at which the available superheat temperature is insufficient to prevent excessive moisture from forming in the low-pressure turbine stages. This condition is resolved by removing the vapor for reheat at constant pressure in the boiler and returning it to the turbine for continued expansion to condenser pressure. The thermodynamic cycle using this modification of the Rankine cycle is called the *reheat cycle*.

**Economizers** Economizers improve boiler efficiency by extracting heat from the discharged flue gases and transferring it to feedwater, which enters the steam generator at a temperature appreciably lower than the saturation-steam temperature.

**Industrial Boilers** Industrial boilers are steam generators that provide power, steam, or both to an industrial plant, in contrast to a utility boiler in a steam power plant. A common configuration is a stationary water-tube boiler in which some of the steam is generated in a convection-section tube bank (also termed a *boiler bank*). In the original industrial boilers, in fact, almost all of the boiling occurred in that section, but now many industrial steam generators of 180,000 kg/h (397,000 lb/h) and greater capacity are radiant boilers. The boiler steam pressure and temperature and feedwater temperature determine the fraction of total heat absorbed in the boiler bank. For a typical coal-fired boiler producing about 90,000 kg/h (198,000 lb/h):

| % total steam in boiler bank | Boiler pressure |      | Steam temperature |      | Feedwater temperature |     |
|------------------------------|-----------------|------|-------------------|------|-----------------------|-----|
|                              | MPa             | psia | K                 | °F   | K                     | °F  |
| 45                           | 1.4             | 200  | 460               | 369  | 389                   | 241 |
| 30                           | 4.1             | 600  | 672               | 750  | 389                   | 241 |
| 16                           | 10.3            | 1500 | 783               | 950  | 450                   | 351 |
| 10                           | 12.4            | 1800 | 811               | 1000 | 450                   | 351 |

The thicker plate for operation at higher pressures increases the cost of the boiler. As a result, it is normally not economical to use a boiler bank for heat absorption at pressures above 10.7 MPa (1550 psia).

Industrial boilers are employed over a wide range of applications, from large power-generating units with sophisticated control systems, which maximize efficiency, to small low-pressure units for space or process heating, which emphasize simplicity and low capital cost. Although their usual primary function is to provide energy in the form of steam, in some applications steam generation is incidental to a process objective, e.g., a chemical recovery unit in the paper industry,

**TABLE 24-14 Solid-Waste Fuels Burned in Industrial Boilers**

| Waste               | HHV, kJ/kg*   |
|---------------------|---------------|
| Bagasse             | 8374–11,630   |
| Furfural residue    | 11,630–13,956 |
| Bark                | 9304–11,630   |
| General wood wastes | 10,467–18,608 |
| Coffee grounds      | 11,397–15,119 |
| Nut hulls           | 16,282–18,608 |
| Rich hulls          | 12,095–15,119 |
| Corncobs            | 18,608–19,306 |
| Rubber scrap        | 26,749–45,822 |
| Leather             | 27,912–45,822 |
| Cork scrap          | 27,912–30,238 |
| Paraffin            | 39,077        |
| Cellophane plastics | 27,912        |
| Polyvinyl chloride  | 40,705        |
| Vinyl scrap         | 40,705        |
| Sludges             | 4652–27,912   |
| Paper wastes        | 13,695–18,608 |

\*To convert kilojoules per kilogram to British thermal units per pound, multiply by  $4.299 \times 10^{-1}$ .

a carbon monoxide boiler in an oil refinery, or a gas-cooling waste-heat boiler in an open-hearth furnace. It is not unusual for an industrial boiler to serve a multiplicity of functions. For example, in a paper-pulp mill, the chemical-recovery boiler is used to convert black liquor into useful chemicals and to generate process steam. At the same plant, a bark-burning unit recovers heat from otherwise wasted material and also generates power.

Industrial boilers burn oil, gas, coal, and a wide range of product and/or waste fuels, some of which are shown in Tables 24-4 and 24-14. Natural gas has become the principal fuel of choice, accounting for approximately 80 percent of all the energy fired in industrial boilers across a range of manufacturing industries (Table 24-15). Coal is the second most prevalent fuel, accounting for about 15 percent of the energy fired. Waste fuels, however, are increasing in importance.

An excellent brief exposition of industrial boilers is presented as Chapter 8 of *Combustion—Fossil Power*, Singer (ed.), 4th ed., Combustion Engineering, Windsor, Conn., 1991.

**Design Criteria** Industrial-boiler designs are tailored to the fuels and firing systems involved. Some of the more important design criteria include:

- Furnace heat-release rates, both  $W/m^3$  and  $W/m^2$  of effective projected radiant surface ( $Btu/[h \cdot ft^3]$  and  $Btu/[h \cdot ft^2]$ )
- Heat release on grates
- Flue-gas velocities through tube banks
- Tube spacings

**TABLE 24-16 Typical Design Parameters for Industrial Boilers**

| Furnace                       |                         | Heat-release rate, $W/m^2$ of EPRS† |                 |
|-------------------------------|-------------------------|-------------------------------------|-----------------|
| Natural gas-fired             |                         | 630,800                             |                 |
| Oil-fired                     |                         | 551,900–630,800                     |                 |
| Coal: pulverized coal         |                         | 220,780–378,480                     |                 |

†Effective projected radiant surface.

‡Not available.

Table 24-16 gives typical values or ranges of these criteria for gas, oil, and coal. The furnace release rates are important, for they establish maximum local absorption rates within safe limits. They also have a bearing on completeness of combustion and therefore on efficiency and particulate emissions. Limiting heat release on grates (in stoker firing) will minimize carbon loss, control smoke, and avoid excessive fly ash.

Limits on flue-gas velocities for gas- or oil-fired industrial boilers are usually determined by the need to limit draft loss. For coal firing, design gas velocities are established to minimize fouling and plugging of tube banks in high-temperature zones and erosion in low-temperature zones.

Convection tube spacing is important when the fuel is residual oil or coal, especially coal with low ash-fusion or high ash-fouling tendencies. The amount of the ash and, even more important, the characteristics of the ash must be specified for design.

Natural-circulation and convection boiler banks are the basic design features on which a line of standard industrial boilers has been developed to accommodate the diverse steam, water, and fuel requirements of the industrial market.

Figure 24-37 shows the amount of energy available for power by using a fire-tube boiler, an industrial boiler, and subcritical- and

supercritical-pressure boilers. Condensing losses decrease substantially, and regeneration of air and feedwater becomes increasingly important in the most advanced central-station boilers.

The boiler designer must proportion heat-absorbing and heat-recovery surfaces in a way to make the best use of heat released by the fuel. Water walls, superheaters, and reheaters are exposed to convection and radiant heat, whereas convection heat transfer predominates in air preheaters and economizers. The relative amounts of these surfaces vary with the size and operating conditions of the boiler.

**Package Boilers** In a fire-tube boiler, the hot combustion products flow through tubes immersed in the boiler water, transferring heat to it. In a water-tube boiler, combustion heat is transferred to water flowing through tubes which line the furnace walls and boiler passages. The greater safety of water-tube boilers has long been recognized, and they have generally superseded fire-tube configurations except for small package boiler designs. Fire-tube package boilers range from a few hundred to 18,200 kg/h (40,000 lb/h) steaming capacity. A fire-tube boiler is illustrated in Figs. 24-38 and 24-39. Water-tube package boilers range from a few hundred to 270,000 kg/h (600,000 lb/h) steaming capacity. A water-tube package boiler is illustrated in Fig. 24-40. The majority of water-tube package boilers use natural circulation and are designed for pressurized firing. The most

significant advantage of shop-assembled or package boilers is the cost benefit associated with use of standard designs and parts.

Package boilers can be shipped complete with fuel-burning equipment, controls, and boiler trim. It may be necessary to ship the larger units in sections, however, and a shop-assembled boiler with a capacity greater than about 109,000 kg/h (240,000 lb/h) is deliverable only by barge. (For a more detailed discussion of shop-assembled boilers, see Singer, 1991, pp. 8.36–8.42.)

**Fluidized-Bed Boilers** Although the furnace of a fluid-bed boiler has a unique design, the system as a whole consists mainly of standard equipment items adapted to suit process requirements. The systems for feedstock preparation and feeding (biomass, coal, sorbent, and sand), ash removal, and ash disposal are very similar to those found in PC boiler plants, the main difference being that the top size of the material being handled is greater. The water-wall boiler enclosure and convection pass tubing are also similar to the designs found in PC boilers. The fluidized-bed plant includes particulate removal equipment such as cyclones, baghouses, and ESPs, with designs similar to those found in other solids-handling process plants.

**Bubbling FBCs** A simplified schematic of a bubbling FBC plant is presented in Fig. 24-41. This design is used primarily for burning biomass, although coal may be cofired to maintain heat release rates when feeding high-moisture feedstocks such as sludges.

The biomass is fed overbed through multiple feed chutes using air jets to help distribute the fuel over the surface of the bed. Variable-speed screw conveyors are usually used to meter the fuel feed rate and control steam output. Feedstocks such as bark and waste wood are chipped to a top size of 25 mm (1 in) to ensure complete combustion. The bed usually consists of sand around 1 m (3 ft) deep. This serves to retain the fuel in the furnace, extending its in-furnace residence time and increasing combustion efficiency. It also provides a heat sink to help maintain bed temperature during periods of fluctuating fuel moisture content.

Biomass fuels, especially forestry products and waste wood, can contain oversized material such as rocks and other debris. If this material is allowed to accumulate, the quality of fluidization deteriorates, resulting in poor fuel mixing and reduced combustion efficiency. To avoid this mal-operation, units typically employ an open-bottom floor design that allows easy solids removal while still ensuring even distribution of the fluidizing air. The fluidizing air (primary combustion air) is fed into large bore pipes extending across the width of the furnace and enters the boiler through a series of nozzles set in the pipes. The pipes are spaced to allow material to drain from all areas of the bed.

The bed temperature control strategies discussed earlier in this section result in the bed operating substoichiometrically. This helps lower the formation of NO<sub>x</sub> but increases the amount of CO formed and the amount of unburned fuel leaving the bed. To complete the combustion process, secondary air is introduced through multiple ports above the bed with the upper furnace height designed to achieve 2- to 3-s flue gas residence time. The velocity of the secondary air should be sufficient to penetrate across the furnace and facilitate thorough mixing with the flue gas leaving the surface of the bed. Although the unburned carbon leaving the furnace is low, the CO is still relatively high at 43 to 128 mg/MJ (0.10 to 0.25 lb/MBtu), which may be a problem in nonattainment areas.

Ammonia injected into the upper furnace is used to promote SNCR reactions to reduce NO<sub>x</sub> emissions. The optimum temperature for

FIG. 24-40 A D-type shop-assembled water-tube boiler. (Combustion Engineering, Inc.)

these reactions is around 830°C (1520°F), but the upper furnace temperature varies depending upon the extent of secondary combustion air usage. To ensure that the ammonia enters into a region at the optimum temperature, multiple levels of injection ports are provided.

**Circulating FBCs** The circulating FBC is the more widely deployed than the bubbling-bed design and at far larger sizes. A simplified schematic for a design with an external heat exchanger is presented in Fig. 24-42. As of 2005 there were over 20 units in the range of 200 to 320 MWe worldwide, and a similar number were in the planning stages.

FIG. 24-41 Simplified flow diagram for bubbling AFBC (with underbed feed system).

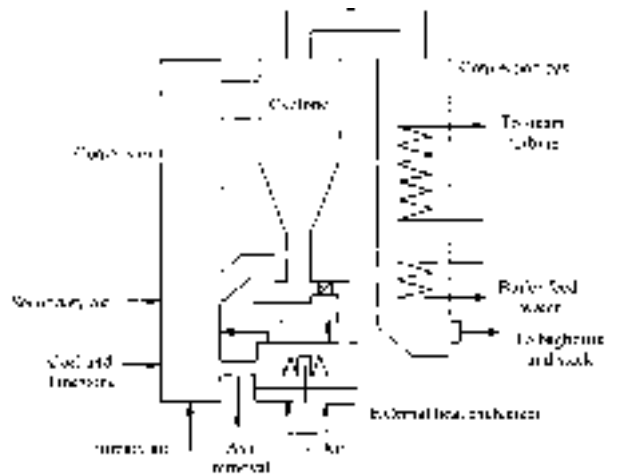

FIG. 24-42 Simplified flow diagram for circulating AFBC (with external heat exchanger).

The most widely used fuels are low-grade coals with high ash and moisture contents, making them unsuitable for use in PC plants. The coal is crushed to a top size of 12 mm (1/2 in), without drying, and fed by gravity into the lower refractory-lined portion of the boiler. The feed points are close to the pressure balance point, and the low backpressure greatly reduces the sealing requirements. In some designs the coal is also introduced into the cyclone ash return lines. The larger units average a feed point for every 23 m<sup>2</sup> (250 ft<sup>2</sup>) of freeboard cross section. The highly turbulent bed facilitates good mixing of the coal across the combustor. The sorbent is prepared to a top size of 1 mm (0.04 in) and dried so that it can be pneumatically fed to the combustor also using one feed point for every 23 m<sup>2</sup> (250 ft<sup>2</sup>) of freeboard cross section. Load control

is achieved primarily by reducing the coal feed rate, with a corresponding reduction in airflow, to reduce the heat release rate. As the heat-transfer area remains unchanged, the furnace temperature falls.

Almost all the particulate matter leaving the boiler is collected by cyclones and recycled to the base of the unit. The number of cyclones varies in different design concepts, but for the larger units one cyclone is provided for 100 to 130 MWe of generating capacity, providing one recycle point for 210 to 290 m<sup>2</sup> (720 to 950 ft<sup>2</sup>) of freeboard cross section. The collected particulate matter is returned against a backpressure of 0.02 MPa (3 psi), through a J-valve. The recycle ratio can be as high as 40:1, corresponding to a relatively long mean particle residence time and accounting for the high performance of circulating units. For bituminous coal combustion, efficiency is close to 99 percent, but like the biomass-fired bubbling beds, CO levels are relatively high at around 43 mg/MJ (0.1 lb/MBtu).

## PROCESS HEATING EQUIPMENT

Many major energy-intensive industries depend on direct-fired or indirect-fired equipment for drying, heating, calcining, melting, or chemical processing. This subsection discusses both direct- and indirect-fired equipment, with the greater emphasis on indirect firing for the process industries.

**Direct-Fired Equipment** Direct-fired combustion equipment transfers heat by bringing the flame and/or the products of combustion into direct contact with the process stream. Common examples are rotary kilns, open-hearth furnaces, and submerged-combustion evaporators. Table 24-17 gives the average energy consumption rates for various industries and processes that use direct heat. Section 12 of this handbook describes and illustrates rotary dryers, rotary kilns, and hearth furnaces. Forging, heat treating, and metal milling furnaces are discussed by Mawhinney (*Marks' Standard Handbook for Mechanical Engineers*, 9th ed., McGraw-Hill, New York, 1987, pp. 7.47-7.52). Other direct-fired furnaces are described later in this section.

**Indirect-Fired Equipment (Fired Heaters)** Indirect-fired combustion equipment (fired heaters) transfers heat across either a metallic or refractory wall separating the flame and products of combustion from the process stream. Examples are heat exchangers (discussed in Sec. 11), steam boilers, fired heaters, muffle furnaces, and melting pots. Steam boilers have been treated earlier in this section, and a subsequent subsection on industrial furnaces will include muffle furnaces.

\*Mixture of direct and indirect firing.

Fired heaters differ from other indirect-fired processing equipment in that the process stream is heated by passage through a coil or tubebank enclosed in a furnace. Fired heaters are classified by function and by coil design.

**Function** Berman [*Chem. Eng.* 85(14):98-104, June 19, 1978] classifies fired heaters into the following six functional categories, providing descriptions that are abstracted here.

**Column reboilers** heat and partially vaporize a recirculating stream from a fractionating column. The outlet temperature of a reboiler stream is typically 477 to 546 K (400 to 550°F).

**Fractionator-feed preheaters** partially vaporize charge stock from an upstream unfired preheater en route to a fractionating column. A typical refinery application: a crude feed to an atmospheric column enters the fired heater as a liquid at 505 K (450°F) and leaves at 644 K (700°F), having become 60 percent vaporized.

**Reactor-feed-stream preheaters** heat the reactant stream(s) for a high-temperature chemical reaction. The stream may be single-phase/single-component [example: steam being superheated from 644 to 1089 K (700 to 1500°F) for styrene-manufacture reactors]; single-phase/multicomponent [example: preheating the feed to a catalytic reformer, a mixture of hydrocarbon vapors and recycle hydrogen, from 700 to 811 K (800 to 1000°F) under pressure as high as 4.1 MPa (600 psia)]; or multiphase/multicomponent [example: a mixture of hydrogen gas and liquid hydrocarbon heated from 644 to 727 K (700 to 850°F) at about 20 MPa (3000 psia) before it enters a hydrocracker].

**Heat-transfer-fluid heaters** maintain the temperature of a circulating liquid heating medium (e.g., a paraffinic hydrocarbon mixture, a Dowtherm, or a molten salt) at a level that may exceed 673 K (750°F).

**Viscous-liquid heaters** lower the viscosity of very heavy oils to pumpable levels.

**Fired reactors** contain tubes or coils in which an endothermic reaction within a stream of reactants occurs. Examples include steam/hydrocarbon reformers, catalyst-filled tubes in a combustion chamber; pyrolyzers, coils in which alkanes (from ethane to gas oil) are cracked to olefins; in both types of reactor the temperature is maintained up to 1172 K (1650°F).

**Coil Design** Indirect-fired equipment is conventionally classified by tube orientation: vertical and horizontal. Although there are many variations of each of these two principal configurations, they all are embraced within seven major types, as follows.

A *simple vertical cylindrical* heater has vertical tubes arrayed along the walls of a combustion chamber fired vertically from the floor. This type of heater does not include a convection section and is inexpensive. It has a small footprint but low efficiency, and it is usually selected for small-duty applications [0.5 to 21 GJ/h (0.5 to 20 10<sup>6</sup> Btu/h)].

*Vertical cylindrical; cross-tube convection* heaters are similar to the preceding type except for a horizontal convective tube bank above the combustion chamber. The design is economical with a high efficiency and is usually selected for higher-duty applications: 11 to 210 GJ/h (10 to 200 10<sup>6</sup> Btu/h).

The *arbor (wicket)* heater is a substantially vertical design in which the radiant tubes are inverted U's connecting the inlet and outlet terminal manifolds in parallel. An overhead crossflow convection bank is usually included. This type of design is good for heating large gas flows with low pressure drop. Typical duties are 53 to 106 GJ/h (50 to 100 10<sup>6</sup> Btu/h).

In the *vertical-tube single-row double-fired* heater, a single row of vertical tubes is arrayed along the center plane of the radiant section that is fired from both sides. Usually this type of heater has an overhead horizontal convection bank. Although it is the most expensive of the fired heater designs, it provides the most uniform heat transfer to the tubes. Duties are 21 to 132 GJ/h (20 to 125 10<sup>6</sup> Btu/h) per cell (twin-cell designs are not unusual).

*Horizontal-tube cabin* heaters position the tubes of the radiant-section-coil horizontally along the walls and the slanting roof for the length of the cabin-shaped enclosure. The convection tube bank is placed horizontally above the combustion chamber. It may be fired from the floor, the side walls, or the end walls. As in the case of its vertical cylindrical counterpart, its economical design and high efficiency make it the most popular horizontal-tube heater. Duties are 11 to 105 GJ/h (10 to 100 10<sup>6</sup> Btu).

In the *horizontal-tube box heater with side-mounted convection tube bank*, the radiant-section tubes run horizontally along the walls and the flat roof of the box-shaped heater, but the convection section is placed in a box of its own beside the radiant section. Firing is horizontal from the end walls. The design of this heater results in a relatively expensive unit justified mainly by its ability to burn low-grade high-ash fuel oil. Duties are 53 to 210 GJ/h (50 to 200  $10^6$  Btu/h).

*Vertical cylindrical helical coil* heaters are hybrid designs that are classified as vertical heaters, but their in-tube characteristics are like those of horizontal heaters. There is no convection section. In addition to the advantages of simple vertical cylindrical heaters, the helical coil heaters are easy to drain. They are limited to small-duty applications: 5 to 21 GJ/h (5 to 20  $10^6$  Btu/h).

Schematic elevation sections of a vertical cylindrical, cross-tube convection heater; a horizontal-tube cabin heater; and a vertical cylindrical, helical-coil heater are shown in Fig. 24-43. The seven basic designs and some variations of them are pictured and described in the reference cited above and by R. K. Johnson [*Combustion* 50(5): 10-16, November 1978].

The design of both radiant and convection sections of fired heaters, along with some equipment descriptions and operating suggestions, are discussed by Berman in *Encyclopedia of Chemical Processing and Design* [McKetta (ed.), vol. 22, Marcel Dekker, 1985, pp. 31-69]. He also treats construction materials, mechanical features, and operating points in three other *Chemical Engineering* articles [all in vol. 85 (1978): no. 17, July 31, pp. 87-96; no. 18, August 14, pp. 129-140; and no. 20, Sept. 11, pp. 165-169].

## INDUSTRIAL FURNACES

Industrial furnaces serve the manufacturing sector and can be divided into two groups. Boiler furnaces, which are the larger group and are used solely to generate steam, were discussed earlier in the subsection

on industrial boilers. Furnaces of the other group are classified as follows: by (1) source of heat (fuel combustion or electricity), (2) function (heating without change of phase or with melting), (3) process cycle (batch or continuous), (4) mode of heat application (direct or indirect), and (5) atmosphere in furnace (air, protective, or reactive, including vacuum). Each will be discussed briefly.

**Source of Heat** Industrial furnaces are either fuel-fired or electric, and the first decision that a prospective furnace user must make is between these two. Although electric furnaces are uniquely suited to a few applications in the chemical industry (manufacture of silicon carbide, calcium carbide, and graphite, for example), their principal use is in the metallurgical and metal-treatment industries. In most cases the choice between electric and fuel-fired is economic or custom-dictated, because most tasks that can be done in one can be done equally well in the other. Except for an occasional passing reference, electric furnaces will not be considered further here. The interested reader will find useful reviews of them in *Kirk-Othmer Encyclopedia of Chemical Technology* (4th ed., vol. 12, articles by Cotchen, Sommer, and Walton, pp. 228-265, Wiley, New York, 1994) and in *Marks' Standard Handbook for Mechanical Engineers* (9th ed., article by Lewis, pp. 7.59-7.68, McGraw-Hill, New York, 1987).

**Function and Process Cycle** Industrial furnaces are enclosures in which process material is heated, dried, melted, and/or reacted. Melting is considered a special category because of the peculiar difficulties that may be associated with a solid feed, a hot liquid product, and a two-phase mixture in between; it is customary, therefore, to classify furnaces as heating or melting.

**Melting Furnaces: The Glass Furnace** Most melting furnaces, electric or fuel-fired, are found in the metals-processing industry, but a notable exception is the glass furnace. Like most melting furnaces, a glass furnace requires highly radiative flames to promote heat transfer to the feed charge and employs regenerators to conserve heat from the high-temperature process [greater than 1813 K (2300°F)].

FIG. 24-43 Representative types of fired heaters: (a) vertical-tube cylindrical with cross-flow-convection section; (b) horizontal-tube cabin; (c) vertical cylindrical, helical coil. (From Berman, *Chem. Eng.* 85:98-104, June 19, 1978.)

FIG. 24-44 Side-port continuous regenerative glass melting furnace.

A typical side-port continuous regenerative glass melting furnace is shown in Fig. 24-44. Side-port furnaces are used in the flat and container glass industries. The burners are mounted on both sides of the furnace and the sides fire alternately. Refractory-lined flues are used to recover the energy of the hot flue gas. The high temperature of the flue gas leaving the furnace heats a mass of refractory material called a *checker*. After the checker has reached the desired temperature, the gas flow is reversed and the firing switches to the other side of the furnace. The combustion air is then heated by the hot checker and can reach 1533 K (2300°F). The cycle of airflow from one checker to the other is reversed approximately every 15 to 30 min.

The glass melt is generally 1 to 2 m (3 to 6 ft) deep, the depth being limited by the need for proper heat transfer to the melt. Container glass furnaces are typically 6 to 9 m (20 to 30 ft) wide and 6 to 12 m (20 to 40 ft) long. Flat glass furnaces tend to be longer, typically over 30 m (100 ft), because of the need for complete reaction of the batch ingredients and improved quality (fewer bubbles). They typically have a melting capacity of 450 to 630 Mg/day (500 to 750 U.S. ton/d), compared to a maximum of 540 Mg/day (600 U.S. ton/d) for container and pressed/blown glass furnaces.

Though the stoichiometric chemical energy requirement for glass-making is only some 2.3 GJ/Mg (2  $10^6$  Btu/U.S. ton) of glass, the inherently low thermal efficiency of regenerative furnaces means that, in practice, at least 7 GJ/Mg (6  $10^6$  Btu/U.S. ton) is required. Of this total, some 40 percent goes to batch heating and the required heat of reactions, 30 percent is lost through the furnace structure, and 30 percent is lost through the stack. The smaller furnaces used in pressed/blown glass melting are less efficient, and energy consumption may be as high as 17.4 TJ/Mg (15  $10^6$  Btu/U.S. ton).

Industrial furnaces may be operated in batch or continuous mode.

**Batch Furnaces** This type of furnace is employed mainly for the heat treatment of metals and for the drying and calcination of ceramic articles. In the chemical process industry, batch furnaces may be used for the same purposes as batch-tray and truck dryers when the drying or process temperature exceeds 600 K (620°F). They are employed

also for small-batch calcinations, thermal decompositions, and other chemical reactions which, on a larger scale, are performed in rotary kilns, hearth furnaces, and shaft furnaces.

**Continuous Furnaces** These furnaces may be used for the same general purposes as are the batch type, but usually not on small scale. The process material may be carried through the furnace by a moving conveyor (chain, belt, roller), or it may be pushed through on idle rollers, the motion being sustained by an external pusher operating on successively entering cars or trays, each pushing the one ahead along the entire length of the furnace and through the exit flame curtains or doors.

#### Furnace Atmosphere and Mode of Heating

**Direct Heating** Industrial furnaces may be directly or indirectly heated, and they may be filled with air or a protective atmosphere, or under a vacuum. Direct heating is accomplished by the hot combustion gases being inside the furnace and therefore in direct contact with the process material. Thus, the material is heated by radiation and convection from the hot gas and by reradiation from the heated refractory walls of the chamber. Three styles of direct firing are illustrated in Fig. 24-45. *Simple direct firing* is used increasingly because of its simplicity and because of improved burners. The *overhead* design allows the roof burners to be so placed as to provide optimum temperature distribution in the chamber. *Underfiring* offers the advantage of the charge's being protected from the flame. The maximum temperature in these direct-heated furnaces is limited to about 1255 K (1800°F) to avoid prohibitively shortened life of the refractories in the furnace.

**Indirect Heating** If the process material cannot tolerate exposure to the combustion gas or if a vacuum or an atmosphere other than air is needed in the furnace chamber, indirect firing must be employed. This is accomplished in a muffle<sup>o</sup> furnace or a radiant-tube furnace (tubes carrying the hot combustion gas run through the furnace).

<sup>o</sup>A muffle is an impenetrable ceramic or metal barrier between the firing chamber and the interior of the furnace. It heats the process charge by radiation and furnace atmosphere convection.

FIG. 24-45 Methods of firing direct-heated furnaces. (From Marks' Standard Handbook for Mechanical Engineers, 9th ed., McGraw-Hill, New York, 1987. Reproduced with permission.)

**Atmosphere** Protective atmosphere within the furnace chamber may be essential, especially in the heat treatment of metal parts. Mawhinney (in *Marks' Standard Handbook for Mechanical Engineers*, 9th ed., McGraw-Hill, New York, 1987, p. 752) lists pure hydrogen, dissociated ammonia (a hydrogen/nitrogen mixture), and six other protective reducing gases with their compositions (mixtures of hydrogen, nitrogen, carbon monoxide, carbon dioxide, and sometimes methane) that are codified for and by the metals-treatment industry. In general, any other gas or vapor that is compatible with the temperature and the lining material of the furnace can be provided in an indirect-fired furnace, or the furnace can be evacuated.

## COGENERATION

Cogeneration is an energy conversion process wherein heat from a fuel is simultaneously converted to useful thermal energy (e.g., process steam) and electric energy. The need for either form can be the primary incentive for cogeneration, but there must be opportunity for economic captive use or sale of the other. In a chemical plant the need for process and other heating steam is likely to be the primary; in a public utility plant, electricity is the usual primary product.

Thus, a cogeneration system is designed from one of two perspectives: it may be sized to meet the process heat and other steam needs of a plant or community of industrial and institutional users, so that the electric power is treated as a by-product which must be either used on site or sold; or it may be sized to meet electric power demand, and the rejected heat used to supply needs at or near the site. The latter approach is the likely one if a utility owns the system; the former if a chemical plant is the owner.

Industrial use of cogeneration leads to small, dispersed electric-power-generation installations—an alternative to complete reliance on large central power plants. Because of the relatively short distances over which thermal energy can be transported, process-heat generation is characteristically an on-site process, with or without cogeneration.

Cogeneration systems will not match the varying power and heat demands at all times for most applications. Thus, an industrial cogeneration system's output frequently must be supplemented by the separate on-site generation of heat or the purchase of utility-supplied

electric power. If the on-site electric power demand is relatively low, an alternative option is to match the cogeneration system to the heat load and contract for the sale of excess electricity to the local utility grid.

Fuel saving is the major incentive for cogeneration. Since all heat-engine-based electric power systems reject heat to the environment, that rejected heat can frequently be used to meet all or part of the local thermal energy needs. Using reject heat usually has no effect on the amount of primary fuel used, yet it leads to a saving of all or part of the fuel that would otherwise be used for the thermal-energy process. Heat engines also require a high-temperature thermal input, usually receiving the working fluid directly from a heating source; but in some situations they can obtain the input thermal energy as the rejected heat from a higher-temperature process. In the former case, the cogeneration process employs a heat-engine topping cycle; in the latter case, a bottoming cycle is used.

The choice of fuel for a cogeneration system is determined by the primary heat-engine cycle. Closed-cycle power systems which are externally fired—the steam turbine, the indirectly fired open-cycle gas turbine, and closed-cycle gas turbine systems—can use virtually any fuel that can be burned in a safe and environmentally acceptable manner: coal, municipal solid waste, biomass, and industrial wastes are burnable with closed power systems. Internal combustion engines, on the other hand, including open-cycle gas turbines, are restricted to fuels that have combustion characteristics compatible with the engine type and that yield combustion products clean enough to pass through the engine without damaging it. In addition to natural gas, butane, and the conventional petroleum-derived liquid fuels, refined liquid and gaseous fuels derived from shale, coal, or biomass are in this category. Direct-coal-fired internal combustion engines have been an experimental reality for decades but are not yet a practical reality technologically or economically.

There are at least three broad classes of application for topping-cycle cogeneration systems:

- Utilities or municipal power systems supplying electric power and low-grade heat (e.g., 422 K [300°F]) for local district heating systems
- Large residential, commercial, or institutional complexes requiring space heat, hot water, and electricity

TABLE 24-18 Cogeneration Characteristics for Heat Engines

| Engine type                   | Size range, MWe/unit | Efficiency at design point | Part-load efficiency | Multifuel capability | Maximum temperature of recoverable heat, °F (°C)* | Recoverable heat, Btu/kWh† | Typical power-to-heat ratio |
|-------------------------------|----------------------|----------------------------|----------------------|----------------------|---|----------------------------|-----------------------------|
| Steam turbine                 |                      |                            |                      |                      |   |                            |                             |
| Extraction-condensing type    | 30–300               | 0.25–0.30                  | Fair                 | Excellent            | 200 (93)–600 (315)‡                               | 11,000–35,000              | 0.1–0.3                     |
| Backpressure type             | 20–200               | 0.20–0.25                  | Fair                 | Excellent            | 200 (93)–600 (315)‡                               | 17,000–70,000              | 0.05–0.2                    |
| Combustion gas turbines       | 10–100               | 0.25–0.30                  | Poor                 | Poor                 | 1000 (538)–1200 (649)                             | 3000–11,000                | 0.3–0.45                    |
| Indirectly fired gas turbines |                      |                            |                      |                      |   |                            |                             |
| Open-cycle turbines           | 10–85                | 0.25–0.30                  | Poor                 | Good                 | 700 (371)–900 (482)                               | 3500–8500                  | 0.4–1.0                     |
| Closed-cycle turbines         | 5–350                | 0.25–0.30                  | Excellent            | Good                 | 700 (371)–900 (482)                               | 3500–8500                  | 0.4–1.0                     |
| Diesel engines                | 0.05–25              | 0.35–0.40                  | Good                 | Fair to poor         | 500 (260)–700 (371)                               | 4000–6000                  | 0.6–0.85                    |

- Large industrial operations with on-site needs for electricity and heat in the form of process steam, direct heat, and/or space heat.

**Typical Systems** All cogeneration systems involve the operation of a heat engine for the production of mechanical work which, in nearly all cases, is used to drive an electric generator. The commonest heat-engine types appropriate for topping-cycle cogeneration systems are:

- Steam turbines (backpressure and extraction configurations)
- Open-cycle (combustion) gas turbines
- Indirectly fired gas turbines: open cycles and closed cycles
- Diesel engines

Each heat-engine type has unique characteristics, making it better suited for some cogeneration applications than for others. For example, engine types can be characterized by:

- Power-to-heat ratio at design point
- Efficiency at design point
- Capacity range
- Power-to-heat-ratio variability
- Off-design (part-load) efficiency
- Multifuel capability

The major heat-engine types are described in terms of these characteristics in Table 24-18.

## ELECTROCHEMICAL ENERGY CONVERSION

Electricity has become as indispensable as heat to the functioning of industrialized society. The source of most of the electricity used is the energy of the fuels discussed earlier in this section: liberated by combustion as heat, it drives heat engines which, in turn, drive electrical generators.

In some instances, however, part of the chemical energy bound in relatively high-enthalpy compounds can be converted directly to electricity as these reactants are converted to products of lower enthalpy (galvanic action). A process in the opposite direction also is possible for some systems: an electric current can be absorbed as the increased chemical energy of the higher-enthalpy compounds (electrolytic action). The devices in which electrochemical energy conversion processes occur are called cells.

Galvanic cells in which stored chemicals can be reacted on demand to produce an electric current are termed *primary cells*. The discharging reaction is irreversible and the contents, once exhausted, must be replaced or the cell discarded. Examples are the dry cells that activate small appliances. In some galvanic cells (called *secondary cells*), however, the reaction is reversible: that is, application of an electrical potential across the electrodes in the opposite direction will restore the reactants to their high-enthalpy state. Examples are rechargeable batteries for household appliances, automobiles, and many industrial applications. Electrolytic cells are the reactors upon which the electrochemical process, electroplating, and electrowinning industries are based.

Detailed treatment of the types of cells discussed above is beyond the scope of this handbook. For information about electrolytic cells, interested readers are referred to Fuller, Newman, Grotheer, and King ("Electrochemical Processing," in *Kirk-Othmer Encyclopedia of Chemical Technology*, 4th ed., vol. 9, Wiley, New York, 1994, pp. 111–197) and for primary and secondary cells, to Crompton (*Battery Reference Book*, 2d ed., Butterworth-Heinemann, Oxford, U.K., 1995). Another type of cell, however, a galvanic cell to which the reactants of an exothermic reaction are fed continuously, in which they react to liberate part of their enthalpy as electrical energy, and from which the products of the reaction are discharged continuously, is called a *fuel cell*. Fuel cell systems for generating electricity in a variety of applications are being commercialized by a number of companies. The rest of this section is devoted to a discussion of fuel cell technology.

### FUEL CELLS

**GENERAL REFERENCES:** W. Vielstich, A. Lamm, H. A. Gasteiger, eds., *Handbook of Fuel Cells*, John Wiley & Sons, 2003. *Fuel Cell Handbook* (Rev. 7), U.S. Department of Energy, DOE/NETL-2004/1206. Liebhafsky and Cairns, *Fuel Cells and Fuel Batteries*, Wiley, New York, 1968. Linden (ed.), *Handbook of Batteries and Fuel Cells*, McGraw-Hill, New York, 1984.

**Background** Energy conversion in fuel cells is direct and simple when compared to the sequence of chemical and mechanical steps in

heat engines. A fuel cell consists of an anode, an electrolyte, and a cathode. On the anode, the fuel is oxidized electrochemically to positively charged ions. On the cathode, oxygen molecules are reduced to oxide or hydroxide ions. The electrolyte serves to transport either the positively charged ions from anode to cathode or the negatively charged ions from cathode to anode. Figure 24-46 is a schematic representation of the reactions in a fuel cell operating on hydrogen and air with a hydrogen-ion-conducting electrolyte. The hydrogen flows over the anode, where the molecules are separated into ions and electrons. The ions migrate through the ionically conducting but electronically insulating electrolyte to the cathode, and the electrons flow through the outer circuit energizing an electric load. The electrons combine eventually with oxygen molecules flowing over the surface of the cathode and hydrogen ions migrating across the electrolyte, forming water, which leaves the fuel cell in the depleted air stream.

A fuel cell has no moving parts. It runs quietly, does not vibrate, and does not generate gaseous pollutants. The idea of the fuel cell is generally credited to Sir William Grove, who lived in the nineteenth century. It took over 100 years for the first practical devices to be built, in the U.S. space program, as the power supply for space capsules and the space shuttle. Commercialization of terrestrial fuel cell systems has only recently begun. Having lower emissions and being more efficient than heat engines, fuel cells may in time become the power source for a broad range of applications, beginning with utility power plants, including civilian and military transportation, and reaching into portable electronic devices.

This slow realization of the concept is due to the very demanding materials requirements for fuel cells. The anodes and cathodes have to be good electronic conductors and must have electrocatalytic properties to facilitate the anodic and cathodic reactions. In addition, the anodes and cathodes must be porous to allow the fuel and oxidant gases to diffuse to the reaction sites, yet they must be mechanically strong enough to support the weight of the fuel cell stacks. The electrolyte must be chemically stable in hydrogen and oxygen, and must

FIG. 24-46 Fuel cell schematic.

have an ionic conductivity of at least 0.1 S/cm. Five classes of electrolytes have been found to meet these requirements: potassium hydroxide, phosphoric acid, perfluorinated sulfonic acid resins, molten carbonates, and oxide-ion-conducting ceramics. Consequently, five types of fuel cell based on these electrolytes have been developed.

**Fuel Cell Efficiency** The theoretical energy conversion efficiency of a fuel cell  $\epsilon^\circ$  is given by the ratio of the free energy (Gibbs function) of the cell reaction at the cell's operating temperature  $\Delta G_t$  to the enthalpy of reaction at the standard state  $\Delta H^\circ$ , both quantities being based on a mole of fuel:

$$\epsilon^\circ = \frac{\Delta G_t}{\Delta H^\circ} \quad (24-54)$$

The enthalpy of reaction is always taken at a temperature of 298 K (77°F), but the product water can be either liquid or gaseous. If it is liquid, the efficiency is based on the higher heating value (HHV), but if the product is gaseous, the efficiency is based on the lower heating value (LHV). If the fuel cell runs on hydrogen and oxygen at 373 K (212°F), the theoretical conversion efficiency is 91 percent LHV or 83 percent HHV. The theoretical efficiency of fuel cells as given in Eq. (24-54) is equivalent to the Carnot efficiency of heat engines with the working medium absorbing heat at the flame temperature of the fuel and rejecting it at 298 K. Owing to materials and engineering limitations, heat engines cannot operate at the Carnot limit. Fuel cells can run at efficiencies near the theoretical values but only at low power density (power produced per unit of active fuel cell area). At higher power densities, the efficiency of fuel cells is constrained by electrical resistances within the bulk and at the interfaces of the materials, and by gas diffusion losses.

When no net current is flowing, the equilibrium potential of the fuel cell is given by the Nernst equation:

$$E^\circ = \frac{-\Delta G_t}{nF} \quad (24-55)$$

where  $E^\circ$  is the electrochemical equilibrium potential,  $V$ ;  $n$  is the number of electrons transferred in the cell reaction (equivalents), and  $F$  is the Faraday constant. If the units of  $\Delta G_t$  are J/mol,  $F$  has the value 96,487 C/mol-equiv. The potential depends on the chemical species of the fuel and the operating temperature. For hydrogen and oxygen, variation of the equilibrium cell potential with temperature is shown in Table 24-19.

When current is flowing, the actual cell operating potential is given by:

$$E = E^\circ - (a_{an} + a_{ca}) - (b_{an} + b_{ca}) \frac{RT}{nF} \ln i - Ai \quad (24-56)$$

where  $a$  and  $b$  are characteristic constants for the electrochemical reactions at the electrode materials; the subscripts an and ca refer to the anode and the cathode, respectively;  $R$  is the gas constant;  $T$  is the cell temperature;  $A$  is the area-specific resistance of the fuel cell; and  $i$  is the current density (current flow per unit of active fuel cell area) in the cell.

Graphs of operating potential versus current density are called *polarization curves*, which reflect the degree of perfection that any particular fuel cell technology has attained. High cell operating potentials are the result of many years of materials optimization. Actual polarization curves will be shown below for several types of fuel cell.

**TABLE 24-19 Thermodynamic Values for  $H_2 + \frac{1}{2}O_2 = H_2O$  (g)**

| Temperature, K | Enthalpy of reaction ( $\Delta H^\circ$ ), kJ/mol | Free energy of reaction ( $\Delta G^\circ$ ), kJ/mol | Equilibrium cell potential ( $E^\circ$ ), V |
|----------------|---|--|---|
| 300            | -241.8  | -228.4   | 1.18  |
| 500            | -243.9  | -219.2   | 1.14  |
| 700            | -245.6  | -208.8   | 1.06  |
| 900            | -247.3  | -197.9   | 1.03  |
| 1100           | -248.5  | -187.0   | 0.97  |
| 1300           | -249.4  | -175.7   | 0.91  |

The actual efficiency of an operating fuel cell is given by:

$$\epsilon = \frac{-nFE}{\Delta H^\circ} U_f \quad (24-57)$$

where  $U_f$  is the electrochemical fuel utilization (amount of fuel converted divided by amount fed to the cell). For pure hydrogen the fuel utilization can be 1.0, but for gas mixtures it is often 0.85. Equations (24-56) and (24-57) show that the efficiency of fuel cells is not constant, but depends on the current density. The more power that is drawn, the lower the efficiency.

When the fuel gas is not pure hydrogen and air is used instead of pure oxygen, additional adjustment to the calculated cell potential becomes necessary. Since the reactants in the two gas streams practically become depleted between the inlet and exit of the fuel cell, the cell potential is decreased by a term representing the log mean fugacities, and the operating cell efficiency becomes

$$\epsilon_{fc} = \frac{nFU_f}{\Delta H^\circ} \left[ E^\circ - \sum a - \sum b \frac{RT}{nF} \ln i - Ai \right] - \frac{RTU_f}{\Delta H^\circ} [v_f \ln(\log \text{mean } \hat{f}_f) + v_{ox} \ln(\log \text{mean } \hat{f}_{ox})] \quad (24-58)$$

The quantities  $v_f$  and  $v_{ox}$  are the stoichiometric coefficients for the fuel cell reaction, and  $\hat{f}_f$  and  $\hat{f}_{ox}$  are the fugacities of fuel and oxygen in their respective streams.

Further, as the current density of the fuel cell increases, a point is inevitably reached where the transport of reactants to or products from the surface of the electrode becomes limited by diffusion. A *concentration polarization* is established at the electrode, which diminishes the cell operating potential. The magnitude of this effect depends on many design and operating variables, and its value must be obtained empirically.

**Design Principles** An individual fuel cell will generate an electrical potential of about 1 V or less, as discussed above, and a current that is proportional to the external load demand. For practical applications, the voltage of an individual fuel cell is obviously too small, and cells are therefore stacked up as shown in Fig. 24-47. Anode/electrolyte/cathode assemblies are electrically connected in series by inserting a bipolar plate between the cathode of one cell and the anode of the next. The bipolar plate must be impervious to the fuel and oxidant gases, chemically stable under reducing and oxidizing conditions, and an excellent electronic conductor. In addition, it is often used to distribute the gases to the anode and cathode surfaces through flow channels cut or molded into it.

The number of fuel cells that are stacked is determined by the desired electrical potential. For 110-V systems it can be about 200 cells. Since a typical fuel cell is about 5 mm (0.2 in) thick, a 200-cell stack assembly (including the end hardware that keeps the unit under compression) is about 2 m (6 ft) tall. The reactant and product gas streams are supplied and removed from the stack by external or internal manifolding. Externally manifolded stacks have shallow trays on each of the four sides to supply the fuel and air and to remove the depleted gases and reaction products. The manifolds are mechanically clamped to the stacks and sealed at the edges. These manifold seals must be gastight, electrically insulating, and able to tolerate thermal expansion mismatches between the stack and the manifold materials as well as dimensional changes due to aging.

Alternatively, reactant and product gases can be distributed to and removed from individual cells through internal pipes in a design analogous to that of filter presses. Care must be exercised to assure an even flow distribution between the entry and exit cells. The seals in internally manifolded stacks are generally not subject to electrical, thermal, and mechanical stresses, but are more numerous than in externally manifolded stacks.

Because fuel cells generate an amount of excess heat consistent with their thermodynamic efficiency, they must be cooled. In low-temperature fuel cells, the cooling medium is generally water or oil, which flows through cooling plates interspaced throughout the stack. In high-temperature cells, heat is removed by the reactant air stream and also by the endothermic fuel reforming reactions in the stack.

FIG. 24-47 Stacking of individual fuel cells.

**Types of Fuel Cells** The five major types of fuel cell are listed in Table 24-20. Each has unique chemical features. The *alkaline fuel cell* (AFC) has high power density and has proven itself as a reliable power source in the U.S. space program, but the alkaline electrolyte reacts with carbon dioxide, which is present in reformed hydrocarbon fuels and air. The *polymer electrolyte fuel cell* (PEFC) and the *phosphoric acid fuel cell* (PAFC) are tolerant of carbon dioxide, but both are sensitive to carbon monoxide (PEFC much more so than PAFC), which is adsorbed onto the platinum catalyst and renders it inactive. Therefore, these three types of fuel cell require pure hydrogen as fuel; and if the hydrogen has been obtained by reforming a fuel such as natural gas, the hydrogen-rich fuel stream must be purified before being introduced into the fuel cell. The *molten carbonate fuel cell* (MCFC) and the *solid oxide fuel cell* (SOFC) can tolerate carbon monoxide and carbon dioxide and can operate on hydrocarbon fuels with minimal fuel processing, but they operate at elevated temperatures.

The operating temperature also affects the fuel cell operating potential in more than one way. A high operating temperature accelerates reaction rates but lowers the thermodynamic equilibrium potential. These effects balance one another, and, in practice, the operating point of any fuel cell is usually between 0.7 and 0.8 V. The cell reactions for the five types of fuel cell are summarized in Table 24-21. It is important to note that in cells with acidic electrolytes (PAFC and PEFC) the product water evolves on the air electrode, but in the alkaline ones (AFC, MCFC, and SOFC) it is generated on the fuel electrode. This has consequences for the system design. Whenever water needs to be recovered for generating hydrogen from hydrocarbon fuels, a condenser is required in PAFC and PEFC systems. In others, the depleted fuel can be recycled.

TABLE 24-20 Fuel Cell Characteristics

| Type of fuel cell | Electrolyte   | Operating temperature |      | Coolant medium |
|-------------------|---|-----------------------|------|----------------|
|                   |   | K                     | °C   |                |
| Alkaline          | KOH   | 363                   | 90   | Water          |
| Polymer           | $\text{CF}_3(\text{CF}_2)_n\text{OCF}_2\text{SO}_3^-$ | 353                   | 80   | Water          |
| Phosphoric acid   | $\text{H}_3\text{PO}_4$                               | 473                   | 200  | Steam/water    |
| Molten carbonate  | $\text{Li}_2\text{CO}_3\text{-K}_2\text{CO}_3$        | 923                   | 650  | Air            |
| Solid oxide       | $\text{Zr}_{0.92}\text{Y}_{0.08}\text{O}_{1.96}$      | 1273                  | 1000 | Air            |

Following is a summary of the materials, operating characteristics, and mode of construction for each type of fuel cell.

**Alkaline Fuel Cell** The electrolyte for NASA's space shuttle orbiter fuel cell is 35 percent potassium hydroxide. The cell operates between 353 and 363 K (176 and 194°F) at 0.4 MPa (59 psia) on hydrogen and oxygen. The electrodes contain platinum-palladium and platinum-gold alloy powder catalysts bonded with polytetrafluoroethylene (PTFE) latex and supported on gold-plated nickel screens for current collection and gas distribution. A variety of materials, including asbestos and potassium titanate, are used to form a micro-porous separator that retains the electrolyte between the electrodes. The cell structural materials, bipolar plates, and external housing are usually nickel-plated to resist corrosion. The complete orbiter fuel cell power plant is shown in Fig. 24-48.

Typical polarization curves for alkaline fuel cells are shown in Fig. 24-49. It is apparent that the alkaline fuel cell can operate at about 0.9 V and 500 mA/cm<sup>2</sup> current density. This corresponds to an energy

TABLE 24-21 Fuel Cell Reaction Electrochemistry

| Type of fuel cell | Conducting ion     | Anode reaction   | Cathode reaction  |
|-------------------|--------------------|--|---|
| Alkaline          | $\text{OH}^-$      | $\text{H}_2 + 2\text{OH}^- \rightarrow 2\text{H}_2\text{O} + 2\text{e}^-$                  | $\frac{1}{2}\text{O}_2 + \text{H}_2\text{O} + 2\text{e}^- \rightarrow 2\text{OH}^-$ |
| Polymer           | $\text{H}^+$       | $\text{H}_2 \rightarrow 2\text{H}^+ + 2\text{e}^-$   | $\frac{1}{2}\text{O}_2 + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{H}_2\text{O}$  |
| Phosphoric acid   | $\text{H}^+$       | $\text{H}_2 \rightarrow 2\text{H}^+ + 2\text{e}^-$   | $\frac{1}{2}\text{O}_2 + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{H}_2\text{O}$  |

FIG. 24-48 Orbiter power plant. (International Fuel Cells.)

conversion efficiency of about 60 percent HHV. The space shuttle orbiter power module consists of three separate units, each measuring 0.35 by 0.38 by 1 m (14 by 15 by 40 in), weighing 119 kg (262 lb), and generating 15 kW of power. The power density is about 100 W/L and the specific power, 100 W/kg.

**Polymer Electrolyte Fuel Cell** The PEFC, also known as the *proton-exchange-membrane fuel cell* (PEMFC), is of great interest for transportation applications because it is capable of high power density and it can deliver about 40 percent of its nominal power at room temperature. These features have made the PEFC a candidate to replace internal combustion engines in automobiles. Methanol, ethanol, hydrogen, natural gas, dimethyl ether, and common transportation fuels such as gasoline are being considered as fuel, but hydrogen is currently preferred. The motivation for developing fuel-cell-powered vehicles is a dramatic reduction in environmentally harmful emissions and high fuel economy.

The electrolyte is a perfluorosulfonic acid ionomer, commercially available under the trade name of Nafion™. It is in the form of a membrane about 0.17 mm (0.007 in) thick, and the electrodes are bonded directly onto the surface. The electrodes contain very finely divided platinum or platinum alloys supported on carbon powder or fibers. The bipolar plates are made of graphite-filled polymer or metal.

Typical platinum catalyst loadings needed to support the anodic and cathodic reactions are currently 0.2 to 0.5 mg/cm<sup>2</sup> of active cell area. Owing to the cost of platinum, substantial efforts have been made to reduce the catalyst loading.

To be ionically conducting, the fluorocarbon ionomer must be “wet”: under equilibrium conditions, it will contain about 20 percent water. The operating temperature of the fuel cell must be

FIG. 24-49 Polarization curves for alkaline fuel cells.

FIG. 24-50 Polarization curves for PEFC stacks.

less than 373 K (212°F), therefore, to prevent the membrane from drying out.

Being acidic, fluorocarbon ionomers can tolerate carbon dioxide in the fuel and air streams; PEFCs, therefore, are compatible with hydrocarbon fuels. However, the platinum catalysts on the fuel and air electrodes are extremely sensitive to carbon monoxide: only a few parts per million are acceptable. Catalysts that are more tolerant to carbon monoxide are being explored. Typical polarization curves for PEFCs are shown in Fig. 24-50.

As mentioned, the primary motivation for the PEFC development was the anticipated applicability in transportation. However, the economics of stationary use are more forgiving, and commercialization of the technology will likely begin as grid-independent power supplies. Figure 24-51 shows a 5-kW PEFC system operating on natural gas.

FIG. 24-51 Natural gas-fueled 5-kW PEFC system. (Courtesy of Plug Power.)

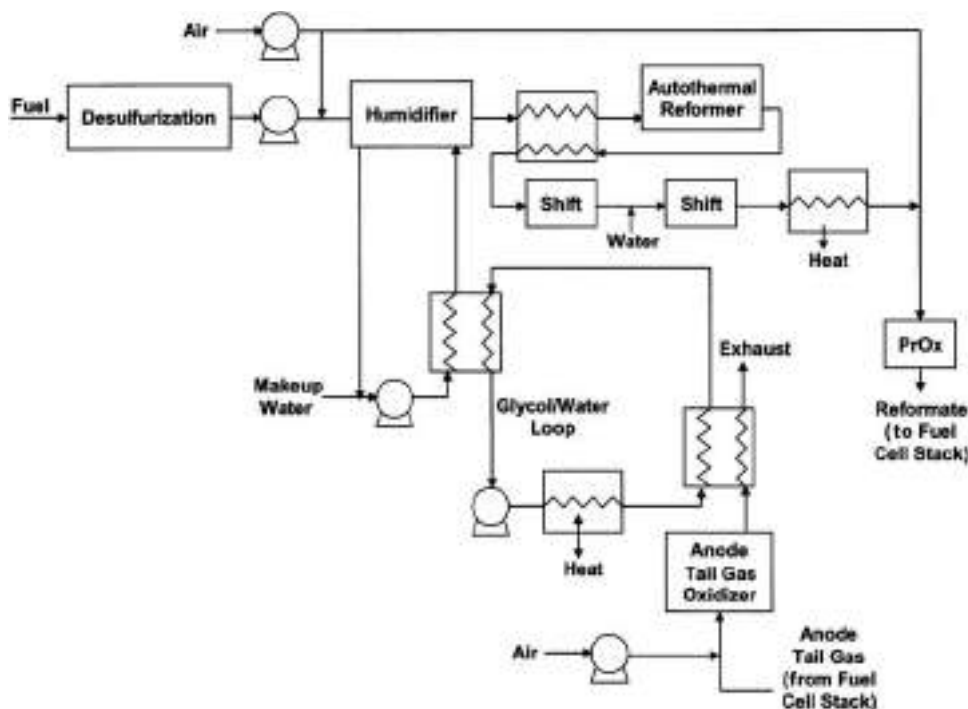

FIG. 24-52 System diagram for reformer-based PEFC system.

The fuel cell stack is visible in the center as a black box, and the fuel processing train is seen on the left. The smaller box on the right contains the power conditioning equipment. Figure 24-52 shows the system diagram for the unit. Natural gas is desulfurized and then mixed with air and steam before entering the autothermal reformer that converts the methane to a mixture of hydrogen, carbon monoxide, and carbon dioxide. Typically this reaction occurs over a catalyst at about 973 K [700°C]. To decrease the carbon monoxide content of this gas, it is cooled to about 623 K [350°C] and reacted with additional water in the so-called shift reactors. Because of the sensitivity of the anode catalyst to carbon monoxide, a preferential oxidation of the remaining carbon monoxide is done before the hydrogen-rich gas is fed to the fuel cell.

About 70 percent of the hydrogen is converted to electricity in the fuel cell stack, and the tail gas is then burned to generate heat which is transferred via a glycol/water loop to the steam generator. The same loop passes through the cooling plates or the fuel cell to remove heat.

A particular version of the PEFC is the **direct methanol fuel cell** (DMFC). As the name implies, an aqueous solution of methanol is used as fuel instead of the hydrogen-rich gas, eliminating the need for reformers and shift reactors. The major challenge for the DMFC is the “crossover” of methanol from the anode compartment into the cathode compartment through the membrane that poisons the electrodes by CO. Consequently, the cell potentials and hence the system efficiencies are still low. Nevertheless, the DMFC offers the prospect of replacing batteries in consumer electronics and has attracted the interest of this industry.

**Phosphoric Acid Fuel Cell** In this type of fuel cell, the electrolyte is 93 to 98 percent phosphoric acid contained in a matrix of silicon carbide. The electrodes consist of finely divided platinum or platinum alloys supported on carbon black and bonded with PTFE latex. The latter provides enough hydrophobicity to the electrodes to prevent flooding of the structure by the electrolyte. The carbon support of the air electrode is specially formulated for oxidation resistance at 473 K (392°F) in air and positive potentials.

The bipolar plate material of the PAFC is graphite. A portion of it has a carefully controlled porosity that serves as a reservoir for phosphoric

acid and provides flow channels for distribution of the fuel and oxidant. The plates are electronically conductive but impervious to gas crossover.

PAFC systems are commercially available from UTC Power as 200-kW stationary power sources operating on natural gas. The stack cross section is  $1 \text{ m}^2$  (10.8 ft<sup>2</sup>). It is about 2.5 m (8.2 ft) tall and rated for a 40,000-h life. It is cooled with water/steam in a closed loop with secondary heat exchangers. Fuel processing is similar to that in a PEFC system, but a preferential oxidizer is not needed. These systems are intended for on-site power and heat generation for hospitals, hotels, and small businesses.

**Molten Carbonate Fuel Cell** The electrolyte in the MCFC is a mixture of lithium/potassium or lithium/sodium carbonates, retained in a ceramic matrix of lithium aluminate. The carbonate salts melt at about 773 K (932°F), allowing the cell to be operated in the 873 to 973 K (1112 to 1292°F) range. Platinum is no longer needed as an electrocatalyst because the reactions are fast at these temperatures. The anode in MCFCs is porous nickel metal with a few percent of chromium or aluminum to improve the mechanical properties. The cathode material is lithium-doped nickel oxide.

The bipolar plates are made from either Type 310 or Type 316 stainless steel, which is coated on the fuel side with nickel and aluminized in the seal area around the edge of the plates. Both internally and externally manifolded stacks have been developed.

In MCFCs, the hydrogen fuel is generated from such common fuels as natural gas or liquid hydrocarbons by steam reforming; the fuel processing function can be integrated into the fuel cell stack because the operating temperature permits reforming using the waste heat. An added complexity in MCFCs is the need to recycle carbon dioxide from the anode side to the cathode side to maintain the desired electrolyte composition. (At the cathode, carbon dioxide reacts with incoming electrons and oxygen in air to regenerate the carbonate ions that are consumed at the anode.) The simplest way is to burn the depleted fuel and mix it with the incoming air. This works well but dilutes the oxygen with the steam generated in the fuel cell. A steam condenser and recuperative heat exchanger can be added to eliminate the steam, but at increased cost.

FIG. 24-53 Polarization curves at different temperatures for 50-cm active length thin-wall SOFCs.

The fuel cell must be cooled with either water or air, and the heat can be converted to electricity in a bottoming cycle. The dc electrical output of the stack is usually converted to ac and stepped up or down in voltage, depending on the application. Analogous to PAFCs, MCFC stacks are about 1 m<sup>2</sup> (10.8 ft<sup>2</sup>) in plan area and quite tall. A stack generates 200 to 300 kW.

**Solid Oxide Fuel Cell** In SOFCs the electrolyte is a ceramic oxide ion conductor, such as yttrium-doped zirconium oxide. The conductivity of this material is 0.1 S/cm at 1273 K (1832°F); it decreases to 0.01 S/cm at 1073 K (1472°F), and by another order of magnitude at 773 K (932°F). Because the resistive losses need to be kept below about 50 mV, the operating temperature of the SOFC depends on the thickness of the electrolyte. For a thickness of 100 μm or more, the operating temperature is 1273 K (1832°F) but fuel cells with thin electrolytes can operate between 973 and 1073 K (1292 and 1472°F).

The anode material in SOFCs is a cermet (metal/ceramic composite material) of 30 to 40 percent nickel in zirconia, and the cathode is

lanthanum manganite doped with calcium oxide or strontium oxide. Both of these materials are porous and mixed ionic/electronic conductors. The bipolar separator typically is doped lanthanum chromite, but a metal can be used in cells operating below 1073 K (1472°F). The bipolar plate materials are dense and electronically conductive.

Typical polarization curves for SOFCs are shown in Fig. 24-53. As discussed earlier, the open-circuit potential of SOFCs is less than 1 V because of the high temperature, but the reaction overpotentials are small, yielding almost linear curves with slopes corresponding to the resistance of the components.

SOFCs can have a planar geometry similar to PEFCs, but the leading technology is tubular, as shown in Fig. 24-54. The advantage of the tubular arrangement is the absence of high-temperature seals.

Like MCFCs, SOFCs can integrate fuel reforming within the fuel cell stack. A prereformer converts a substantial amount of the natural gas using waste heat from the fuel cell. Compounds containing sulfur (e.g., thiophene, which is commonly added to natural gas as an odorant)

FIG. 24-54 Configuration of the tubular SOFC. (Courtesy of Westinghouse Electric Corporation.)

FIG. 24-55 SOFC 25-kW system package. (Courtesy of Westinghouse Electric Corporation.)

must be removed before the reformer. Typically, a hydrodesulfurizer combined with a zinc oxide absorber is used.

The desulfurized natural gas is mixed with the recycled depleted fuel stream containing steam formed in the fuel cell. About 75 percent of the methane is converted to hydrogen and carbon monoxide in the prereformer. The hydrogen-rich fuel is then passed over the

fuel cell anode, where 85 percent is converted to electricity. The balance is burned with depleted air in the combustion zone.

The hot combustion gas preheats the fresh air and the prereformer, and can be used further to generate steam. The system is cooled with 200 to 300 percent excess air. A 25-kW SOFC generator system is shown in Fig. 24-55.

## ENERGY RECOVERY

Most processing energy enters and then leaves the process as energy, separate from the product. The energy enters as electricity, steam, fossil fuels, etc. and then leaves, released to the environment as heat, through "coolers," hot combustion flue gases, waste heat, etc. Recovering heat to be used elsewhere in the process is important to increase process efficiency and minimize cost. Minimizing the total annualized costs for this flow of energy through the process is a complex engineering task in itself, separate from classic process design. Since these costs include the costs for getting energy into and out of the process, they should be evaluated together, as elements integrated within a larger system. Such a holistic system evaluation impacts how the overall project will be designed (utilities supply, reaction and separations design, pinch analyses, 3D process layout, plot plan, etc.). Therefore, evaluation and selection of the process energy technology system should be performed at the start of the project design cycle, during **technology selection VIP** (see the subsection "Value-Improving Practices" in Sec. 9), when the **potential to influence project costs exists at its maximum value**.

Following the 1970s energy crisis, enhanced technology systems have been developed which can **significantly reduce the annualized costs for process energy**. Several of these technologies are presented below, because they are broadly applicable, have a rapid payback, and can make a significant reduction in overall annualized energy costs. Wet surface air coolers (WSACs), an evaporative cooling technology, are presented in Sec. 12.

### ECONOMIZERS

Economizers improve boiler thermal efficiency by recovering heat from the combustion flue gases exhausted from the steam boiler section. The recovered heat is used to heat colder streams (heat sinks), before ultimate discharge of the waste gas to atmosphere. This recovered heat displaces the need to burn additional fuel to heat these same streams.

Normally, after being heated, these streams are used in the boiler area (deaerator feedwater, cold return condensate, boiler feedwater, RO feedwater) or in the combustion chamber (air preheat). However, economizers can be used to recover and supply heat elsewhere, such as hot process water or hot utility water, especially as used in the food processing and pulp/paper industries. Additionally, recovered flue gas waste heat can be used indirectly; i.e., remote process streams can be heated locally with hot steam condensate, and then the cooled return steam condensate can be reheated in the flue gas economizer. An

FIG. 24-56 Calculated sulfuric acid dew points, as a function of  $\text{SO}_3$  content, for various flue gas water vapor concentrations. (Courtesy W. M. M. Huijbregts, 2004.)

extension of these concepts is provided by the application of using hot water to vaporize LNG: hot-water-based liquid is used to vaporize the process stream [LNG: stored near 122 K ( $-151^\circ\text{C}$ ), returning near 273 K ( $0^\circ\text{C}$ )] to the hot water heater. Before entering the hot water heater, the cooled stream recovers flue gas waste heat in a condensing economizer.

**Acid Dew Point** For fossil fuels, the acid dew point temperature is that temperature at which the actual mixed acid vapor pressure equals the mixed acid vapor saturation pressure. The mixed acid dew point can be approximated by the sulfuric acid dew point (Fig. 24-56). It can be described as a function of the  $\text{SO}_3$  and water content of the flue gas (Huijbregts). These concentrations result from the sulfur, hydrogen, and free water content of the fuel; the relative humidity of the air; and the amount of excess air used. Using the equation of Verhoff, where  $T$  is degrees K and  $P$  is mm Hg (see Okkes, A.G.):

$$T_{\text{dew}}(\text{SO}_3) = 1000 / [2.276 - 0.0294 \ln(P_{\text{H}_2\text{O}}) - 0.0858 \ln(P_{\text{SO}_3}) + 0.0062 \ln(P_{\text{H}_2\text{O}} P_{\text{SO}_3})] \quad (24-59)$$

The corrosiveness of flue gas condensate is further complicated by the presence of other components ( $\text{Cl}^-$ ,  $\text{NO}_3^-$ , etc.). The sources of these components can be either the fuel or the combustion air (salt, ammonia, Freon, chlorine, chlorinated VOCs, etc.), usually producing a more corrosive condensate.

**Water Dew Point** For flue gas, the water dew point is that temperature at which the actual water vapor pressure equals the water saturation vapor pressure. Cooling the flue gas below this temperature will result in the formation of liquid water [or ice, below 273 K ( $0^\circ\text{C}$ )]. For example, burning natural gas with 3 percent excess oxygen (15 percent excess air), the flue gas water dew point would be (Fig. 24-57)  $\sim 330$  K ( $56.7^\circ\text{C}$ ).

**Boiler Thermal Efficiency** Traditionally, boiler thermal efficiency is calculated  $Q_{\text{OUT}}/Q_{\text{IN}}$ , where  $Q_{\text{IN}}$  is the LHV (lower heating value) of the fuel. A rule of thumb for economizers is that boiler efficiency increases by  $\sim 1$  percent for every  $22^\circ\text{C}$  ( $40^\circ\text{F}$ ) drop in temperature of the dry flue gas. These two statements do not reveal the considerable quantity of **additional heat**, available to be recovered through **condensation of the water vapor** in the flue gas, which is lost to atmosphere with hot flue gas. Based on fuel HHV (higher heating value), the total latent heat loss can be substantial: an additional 9.6 percent (natural gas), 8.0 percent (propane), 6.5 percent (heating oil).

**Conventional Economizers** Conventional economizers can be constructed from relatively inexpensive materials, such as low-alloy carbon steels, if they will be operated dry on the gas side, with flue gas side metal temperatures above the acid dew point. This practice is done to protect the economizer from corrosion, caused by the acidic flue gas condensate. Conventional economizers can also be con-

FIG. 24-57 Calculated flue gas water vapor dew points, for different fuel types, as a function of excess air [Orimulsion (28.3% water), Pittsburgh Seam 8 (5% water)]. (Courtesy T. A. Butcher, US DOE; [www.bnl.gov](http://www.bnl.gov).)

structed from more expensive materials, and can be operated below the acid dew point, but above the water dew point. This practice permits greater heat recovery, but with a generally lower payback. A compromise practice for operation below the acid dew point is to use less expensive but less corrosion-resistant materials, accepting an accelerated rate of corrosion, and periodically replacing the damaged heat-transfer surfaces when needed. Nevertheless, when high-sulfur fuel is burned (oil, coal, etc.), typically the water inlet feed to a conventional economizer is preheated to a temperature above the anticipated acid dew point.

**Condensing Economizers** Flue gas condensing waste heat economizers are designed to operate **below the flue gas water dew point**. This temperature can range from about 316 K ( $43^\circ\text{C}$ ) to 333 K ( $60^\circ\text{C}$ ), depending on the amount of hydrogen and water in the fuel, the amount of excess combustion air used, and the humidity of the air. [Higher flue gas water dew points can be encountered for other industrial applications, such as product driers, fryers (food processing), waste water incinerators, etc.] Such economizers recover **flue gas sensible heat** as well as **water vapor latent heat** from the hot flue gas. Fuel consumption is reduced in proportion to the efficiency increase.

Condensing economizers are constructed from inexpensive, but durable, corrosion-resistant materials. Extensive materials testing has been performed for operation in this service, including for coal combustion (Lahtvee, Ball, Razgaitis, and Butcher). The metallurgy for the tube-side liquid is determined by the liquid chemistry requirements (usually water-based liquid): 304 stainless steel is typical.

For gas-side materials, one available technology employs Teflon-covered metal tubing and Teflon tube sheets. This technology is often operated across both the acid and water dew points, and can accept inlet gas temperatures to 533 K ( $260^\circ\text{C}$ ). Typical applications may achieve a cold-end  $\Delta T$  below  $45^\circ\text{C}$  ( $80^\circ\text{F}$ ), improve the boiler thermal efficiency by  $\sim 10$  percent (LHV basis), and have a simple payback of 2 to 3 years, based on **fuel avoidance** (Figs. 24-58 and 24-59).

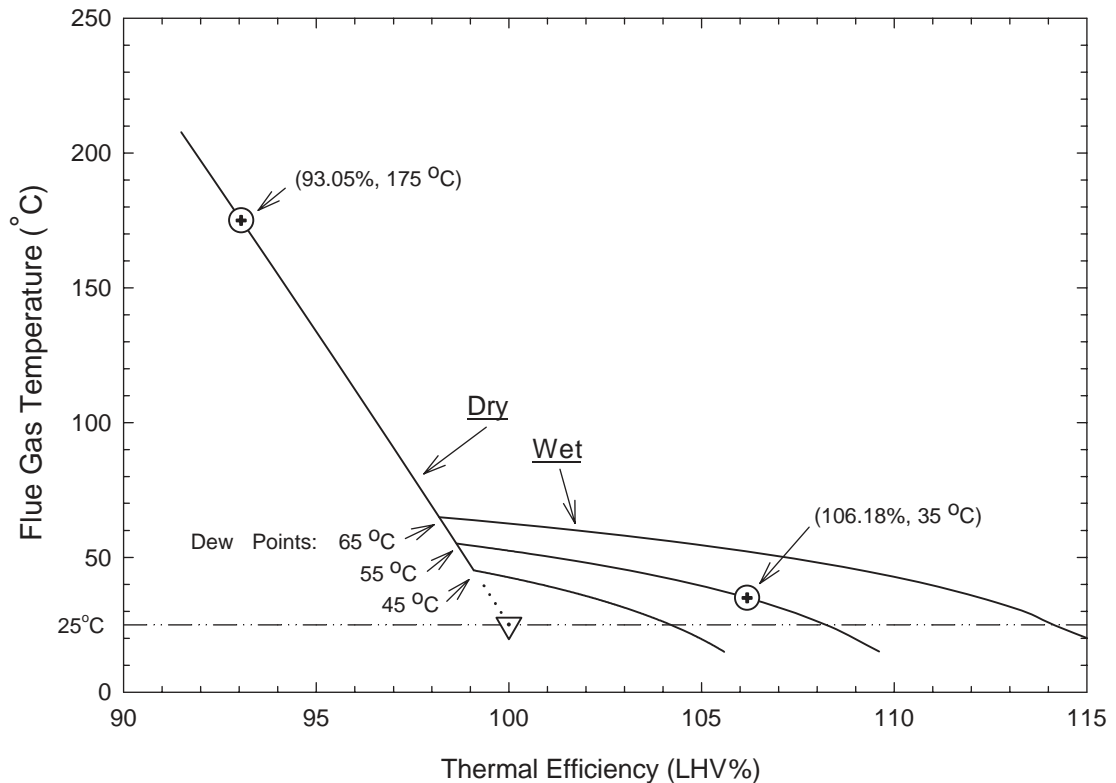

A second technology employs metallic finned tubing, extruded over the water tubing. Aluminum 1000 series fins are preferred, for heat-transfer reasons in natural gas applications, but stainless steel (or other material) fins are used for higher temperatures and/or more corrosive flue gas. This second technology both is less expensive and has better heat transfer (per  $\text{ft}^2$ ). Consequently, for the same payback the cold-end approach can be lower, and the water outlet temperature and the boiler efficiency improvement higher. Flue gas condensate from combustion of natural gas typically has a pH of  $\sim 4.3$ , and aluminum fins are suitable. For more acidic (or erosive) flue gas conditions, other metallurgy (Incoloy® 825 and Hastelloy®), or a Hersite or equivalent coating, may be used to prevent corrosion damage (Fig. 24-60).

**FIG. 24-58** Standard equipment arrangement, flue gas condensing economizer waste heat recovery system (flow: left to right). The ID fan draws hot flue gas from the boiler, propelling it into the top of the condensing economizer. (Courtesy CHX Condensing Heat Exchanger Co.; [www.chxheat.com](http://www.chxheat.com).)

Flue gas condensate at different temperatures, compositions and relative corrosivity condenses and exists at different positions within the condensing economizer. These positions are not fixed in space or time, but move back and forth, in response to changing load conditions

in either stream. Condensing economizers are typically equipped with water spray nozzles for periodic washdown of the flue gas side, to be used (infrequently) for natural gas combustion, but more frequently for services having heavier pollutant loading, such as oil, coal, etc. Over

**FIG. 24-59** Characteristic curves for boiler thermal efficiency as a function of flue gas effluent temperature and flue gas water dew points. Based on the LHV of a fuel, and stoichiometric reaction, 100 percent efficiency would be achieved if sufficient combustion heat were recovered and removed, so that the temperature of the effluent flue gas was reduced to 25°C. For a flue gas with a 55°C dew point, recovering additional heat via condensation by cooling from 175 to 35°C (as shown) would increase the overall efficiency by more than 13 percent. (Courtesy Combustion & Energy Systems, Ltd.; [www.condenergy.com](http://www.condenergy.com).)

**FIG. 24-60** Effect of corrosion on 1100-H14 aluminum alloy by various chemical solutions. Observe the minimal corrosion in the pH range from 4.0 to 9.0. The low corrosion rates in acetic acid, nitric acid, and ammonium hydroxide demonstrate that the nature of the individual ions in solution is more important than the degree of acidity or alkalinity. (With permission from ASM International; [www.asminternational.org](http://www.asminternational.org). Courtesy of Combustion & Energy Systems, Ltd.; [www.condenergy.com](http://www.condenergy.com).)

200 such heat exchangers have been installed, some in service for more than 20 years (2005). This technology is suitable for heat recovery applications of any magnitude.

Several **environmental benefits** are gained through employment of this condensing technology. Burning less fuel proportionally reduces **collateral combustion emissions** ( $\text{NO}_x$ ,  $\text{SO}_x$ ,  $\text{CO}$ ,  $\text{CO}_2$  and particulates, including PM-2.5). Additionally, **flue gas pollutant removal** occurs in the condensing economizer, as has been extensively investigated, characterized, and modeled by the U.S. DOE (Butcher et al.) including applications burning coal and Orimulsion. Typically, the condensate will contain most (by mass, >90 percent) of the highly dissociated inorganic matter ( $\text{H}_2\text{SO}_4$ ,  $\text{HCl}$ ,  $\text{HNO}_3$ ,  $\text{HNO}_2$ ,  $\text{NH}_3$ , salts, etc.) and the **larger-diameter particulates** (>10  $\mu\text{m}$ ) and a lower but substantial fraction (>60 percent) of the **smaller-diameter particulates** (<5  $\mu\text{m}$ ). Such gross pollutant removal can be a cost effective first stage for a traditional air pollution control system, by reducing the volume of the flue gas to be treated (water content and temperature) as well as reducing the concentration of the pollutants in the flue gas to be treated downstream. Unlike spray quenching, such indirect quench-cooling segregates the flue gas pollutants from the cooling system fluid, generating a much smaller, concentrated waste water stream for subsequent waste treatment. Although pollutant removal percentages are high, they are functions of the specific real-time mass- and heat-transfer conditions within the economizer. Condensate treatment from boiler economizers normally is neutralization, often using the boiler blowdown, and release to the sewer and sewage treatment.

## REGENERATORS

Storage of heat is a temporary operation since perfect thermal insulators are unknown; thus, heat is absorbed in solids or liquids as sensible or latent heat to be released later at designated times and conditions. The collection and release of heat can be achieved in two modes: on a batch basis, as in the checkerbrick regenerator for blast furnaces, or on a continuous basis, as in the Ljungstrom air heater.

**Checkerbrick Regenerators** Preheating combustion air in open-hearth furnaces, ingot-soaking pits, glass-melting tanks, by-product coke ovens, heat-treating furnaces, and the like has been universally carried out in regenerators constructed of fireclay, chrome, or silica bricks of various shapes. Although many geometric arrangements have been used in practice, the so-called basketweave design has been adopted in most applications.

**Blast-Furnace Stoves** Blast-furnace stoves are used to preheat the air that is blown into a blast furnace. A typical blast furnace, producing 1500 Mg (1650 U.S. ton) of pig iron per day, will be blown with 47.2  $\text{m}^3/\text{s}$  (100,000 std  $\text{ft}^3/\text{min}$ ) of atmospheric air preheated to temperatures ranging in normal practice from 755 to 922 K (900 to 1200°F). A set of four stoves is usually provided, each consisting of a vertical steel cylinder 7.3 m (24 ft) in diameter, 33 m (108 ft) high, topped with a spherical dome. Characteristic plan and elevation sections of a stove are shown in Fig. 24-61. The interior comprises three regions: in the cylindrical portion, (1) a side combustion chamber,

**FIG. 24-61** Blast-furnace stove.

lens-shaped in cross section, bounded by a segment of the stove wall and a mirror-image bridgewall separating it from (2) the chamber of the cylinder that is filled with heat-absorbing checkerbrick, and (3) the capping dome, which constitutes the open passage between the two chambers.

The heat-exchanging surface in each stove is just under  $11,500 \text{ m}^2$  ( $124,000 \text{ ft}^2$ ). In operation, each stove is carried through a two-step 4-h cycle. In a 3-h *on-gas* step, the checkerbricks in a stove are heated by the combustion of blast-furnace gas. In the alternating *on-wind* 1-h step, they are cooled by the passage of cold air through the stove. At any given time, three stoves are simultaneously on gas, while a single stove is on wind.

At the start of an on-wind step, about one-half of the air, entering at  $366 \text{ K}$  ( $200^\circ\text{F}$ ), passes through the checkerbricks, the other half being bypassed around the stove through the cold-blast mixer valve. The gas passing through the stove exhausts at  $1366 \text{ K}$  ( $2000^\circ\text{F}$ ). Mixing this with the unheated air produces a blast temperature of  $811 \text{ K}$  ( $1000^\circ\text{F}$ ). The temperature of the heated air from the stove falls steadily throughout the on-wind step. The fraction of total air volume bypassed through the mixer valve is continually decreased by progressively closing this valve, its operation being automatically regulated to maintain the exit gas temperature at  $811 \text{ K}$ . At the end of 1 h of on-wind operation, the cold-blast mixer valve is closed, sending the entire blast through the checkerbricks.

**Open-Hearth and Glass-Tank Regenerators** These contain checkerbricks that are modified considerably from those used in blast-furnace stoves because of the higher working temperatures, more drastic thermal shock, and dirtier gases encountered. Larger bricks form flue cross sections five times as large as the stove flues, and the percentage of voids in the checkerbricks is 51 percent, in contrast to 32 percent voids in stoves. The vertical height of the flues is limited by the elevation of the furnace above plant level. Short flues from 3 to 4.9 m (10 to 16 ft) are common in contrast to the 26- to 29-m (85- to 95-ft) flue lengths in blast-furnace stoves.

As a result of the larger flues and the restricted surface area per unit of gas passed, regenerators employed with this type of furnace exhibit much lower efficiency than would be realized with smaller flues. In view of the large amount of iron oxide contained in open-hearth exhaust gas and the alkali fume present in glass-tank stack gases, however, smaller checkerbrick dimensions are considered impractical.

**Ljungstrom Heaters** A familiar continuous regenerative-type air heater is the Ljungstrom heater (Fig. 24-62). The heater assembly consists of a slow-moving rotor embedded between two peripheral housings separated from one another by a central partition. Through one side of the partition a stream of hot gas is being cooled, and, through the other side a stream of cold gas is being heated. Radial and circumferential seals sliding on the rotor limit the leakage between the streams. The rotor is divided into sectors, each of which is tightly packed with metal plates and wires that promote high heat-transfer rates at low pressure drop.

These heaters are available with rotors up to 6 m (20 ft) in diameter. Gas temperatures up to  $1255 \text{ K}$  ( $1800^\circ\text{F}$ ) can be accommodated. Gas face velocity is usually around  $2.5 \text{ m/s}$  ( $500 \text{ ft/min}$ ). The rotor height depends on service, efficiency, and operating conditions but usually is between 0.2 and 0.91 m (8 and 36 in). Rotors are driven by small motors with rotor speed up to 20 r/min. Heater effectiveness can be as high as 85 to 90 percent heat recovery. Ljungstrom-type heaters are used in power-plant boilers and also in the process industries for heat recovery and for air-conditioning and building heating.

**Regenerative Burners** In these systems a compact heat storage regenerator (containing ceramic balls, for example) is incorporated into the burner. Operating in pairs, one burner fires while the other exhausts: combustion air is preheated in the regenerator in the firing burner and furnace gas gives up heat to the regenerator in the exhausting burner (see Fig. 24-63). Burner operations are switched periodically. Such systems can yield combustion air preheats between  $933 \text{ K}$  ( $1220^\circ\text{F}$ ) and  $1525 \text{ K}$  ( $2282^\circ\text{F}$ ) for furnace temperature between  $1073 \text{ K}$  ( $1472^\circ\text{F}$ ) and  $1723 \text{ K}$  ( $2642^\circ\text{F}$ ), respectively.

FIG. 24-62 Ljungstrom air heater.

FIG. 24-63 Schematic of a regenerative burner system. (North American Manufacturing Co.)

Corresponding fuel savings compared to cold-air firing will vary approximately from 30 to 70 percent.

**Miscellaneous Systems** Many other systems have been proposed for transferring heat regeneratively, including the use of high-temperature liquids and fluidized beds for direct contact with gases, but other problems which limit industrial application are encountered. These systems are covered by methods described in Secs. 11 and 12 of this handbook.

## RECUPERATORS

Regenerators are by nature intermittent or cycling devices, although, as set forth previously, the Ljungstrom design avoids interruption of the fluid stream by cycling the heat-retrieval reservoir between the hot and cold fluid streams. Truly continuous counterparts of regenerators exist, however, and they are called *recuperators*.

The simplest configuration for a recuperative heat exchanger is the metallic radiation recuperator. An inner tube carries the hot exhaust gases and an outer tube carries the combustion air. The bulk of the heat transfer from the hot gases to the surface of the inner tube is by radiation, whereas that from the inner tube to the cold combustion air is predominantly by convection.

Shell-and-tube heat exchangers (see Sec. 11) may also be used as recuperators; convective heat transfer dominates in these recuperators. For applications involving higher temperatures, ceramic recuperators have been developed. These devices can allow operation at up to 1823 K (2822°F) on the gas side and over 1093 K (1508°F) on the air side. Early ceramic recuperators were built of furnace brick and cement, but the repeated thermal cycling caused cracking and rapid deterioration of the recuperator. Later designs have used various approaches to overcome the problems of leakage and cracking. In one configuration, for example, silicon carbide tubes carry the combustion air through the waste gas, and flexible seals are used in the air headers. In this manner, the seals are maintained at comparatively low temperatures and the leakage rate can be reduced to a few percent of the total flow.

## TURBINE INLET (AIR) COOLING

**GENERAL REFERENCES:** See "Bibliography" at <http://www.turbineinletcooling.org/resources>.

Turbine inlet cooling (TIC) can increase gas turbine (GT) power output on a hot day by 10 to 30 percent, while improving (reducing) the turbine heat rate (kJ/kW<sub>e</sub>) by as much as 5 percent. By increasing the air compressor inlet air density, turbine inlet air cooling is the most cost-effective method for increasing turbine gross power output, for fixed-altitude GTs.

GTs are "constant-volume machines," such that a fixed-speed GT air compressor section draws a nearly constant volumetric flow of inlet air, independent of ambient air conditions. Air density drops with increased altitude (reduced barometric pressure), increased ambient temperature, and, to a lesser degree, increased water content (specific humidity).

Increasing the air density increases the GT inlet air mass flow. For a given stoichiometric fuel-to-air-ratio and a given combustion temperature, increased air mass flow allows increased fuel flow, resulting in increased GT power output. Additionally, compressor efficiency increases with decreased air temperatures, resulting in less parasitic compressor shaft work consumed and greater net turbine power output. Therefore, TIC increases net incremental power output faster than incremental fuel consumption, resulting in improved overall fuel efficiency (reduced heat rate); see Fig. 24-64.

**Evaporative Technologies** These TIC technologies cool the inlet air by vaporizing water in direct contact with the inlet air, using the latent heat of vaporization of water. These technologies either spray water directly into the airstream as a fog or mist or evaporate the water from fixed wetted media placed in the airstream.

Performance of these technologies is typically an 85 percent approach to the ambient wet-bulb temperature ( $T_{WB}$ ) from the ambient dry-bulb temperature ( $T_{DB}$ ), limited to a 3°F approach to the ambient  $T_{WB}$ . For locations with high  $T_{DB}$  and low  $T_{WB}$ , the cooling benefit can be significant. For locations with humid conditions, the relative cooling achievable by evaporative technologies can be very limited. Additionally, on a given day, the relative changes in hourly  $T_{DB}$  and  $T_{WB}$  will result in variable GT peak power output.

Evaporative TIC technologies have the minimum installed and operating costs. The operating electric parasitic load is generally considered insignificant. Water chemistry management is crucial to prevent maintenance problems caused by dissolved or suspended matter in the water, fouling either the evaporation media or the turbines themselves.

**Refrigeration Technologies** These TIC technologies indirectly cool the inlet air, typically using either chilled water or a vaporizing refrigerant, in a finned coil heat exchanger placed in the incoming airstream. Refrigeration technologies can achieve and maintain much lower air compressor inlet temperatures, largely independent of changing ambient conditions (Fig. 24-65). Best design practices (ice formation / consequent GT damage) have restricted the OEM recommended minimum inlet air cooling temperatures to the 5° to 10°C [41° to 50°F] range. Refrigeration can be supplied by either absorption or mechanical chillers. Absorption chillers employ either LiBr or ammonia absorption. Electrically driven centrifugal packaged chiller systems, using chilled water as a secondary refrigerant, account for the majority of refrigeration machine types. R-123, R-134a, and R-717 are the most common refrigerants offered by vendors. Several installations have used direct refrigeration through R-22 or ammonia (R-717) vaporization in the TIC air coil, with refrigerant condensation in a wet surface air cooler (WSAC) or an air-cooled condenser. Site-specific sources of cooling (the heat sink), such as LNG vaporization, have also been used. The water condensate generated by cooling inlet air below the ambient dew point can be employed as makeup water for a cooling tower or a WSAC.

While refrigeration technologies can provide a near-constant GT inlet air temperature, and thus a nearly constant GT power output, refrigeration TIC systems are significantly more expensive than evaporative systems. However, the incremental net power output from the refrigeration system, when measured on a unit cost basis (\$ per kW<sub>e</sub>),

**FIG. 24-64** Effect of inlet air ambient temperature on the power output of a typical GT. If ambient air at 95°F (35°C) were cooled to 50°F (10°C), the gross GT power output would be increased by approximately 22 percent, and the gross heat rate improved by 3.7 percent. Operated at its ISO conditions [15°C (59°F) at sea level], GT rated performance is 100 percent. (*Turbine Air Systems; www.tas.com.*)

costs much less than the unit cost of the GT itself, thereby decreasing the overall unit cost of the GT plant. Refrigeration technologies require a significant energy input to operate. In the case of electric-driven chillers, the parasitic electric load can consume 10 percent to 15 percent of the GT gross incremental increase in power. Therefore, the net overall plant incremental output, after allowance for the refrigeration system parasitic load, is used for evaluating the economics of these systems.

**Thermal Energy Storage (TES)** A TES system consists of an insulated cold storage tank and a chiller, generating ice or chilled water, which is accumulated in the tank. A TES system is typically installed when TIC is required for only a limited number of operating hours per day. The **principal TES benefit** is that the *net* electrical peak output of the power plant is maximized, by shifting the parasitic electric power loss (chiller power demand) from the period of peak demand (midday) to the off-peak hours (night). A **second benefit** is a reduced overall capital cost for a smaller chiller (usually half-sized) because the smaller chiller is operated either continuously (partial storage) or over a nighttime period (full storage). A **third benefit** is

the reduced operating costs, stemming from the ability to use lower-value off-peak power for the chilling load. A **fourth benefit** is that the chiller will typically perform better during the nighttime off-peak period, due to lower ambient temperatures, reducing the energy required for refrigerant compression. A **fifth benefit** is the ability to increase or decrease generation capacity in a short time period, when called upon, to stabilize the transmission system or grid the plant is tied into. However, a TES site footprint may be larger, to include the TES storage tank.

**Summary** Evaporative technologies have the lowest capital and operating costs, but their benefit is limited by ambient conditions. They are most effective where the peak  $T_{WB}$  is lowest, especially at times of peak demand, as are found in hot, arid regions. Refrigeration technologies can achieve and maintain constant lower temperatures, independent of ambient conditions. However, they have higher initial capital and operating costs. Although refrigeration technologies are favored for use in warm, humid regions, where both the peak daytime  $T_{WB}$  and air conditioning demand are highest, they have been selected and installed in more northern temperate latitudes (Canada) and arid climates as well. TES and other hybrids, which combine various technologies, are used to minimize the overall annualized costs for TIC systems. The unit costs for TIC technologies are substantially lower than are the unit costs for new GTs. Therefore, the installation of a new TIC technology to an existing GT system may offer the lowest-cost choice for increasing the output capability of that older system. For new installations, the inclusion of an optimal TIC technology with the new GT should result in minimizing the annualized cost for output power. Typical unit costs for TIC options range from \$25 (evaporative) to \$200 (refrigeration) per  $kW_e$  of incremental power output, vs. \$300 to \$500 per  $kW_e$  for a new single cycle GT. Selection of the most suitable TIC option for any given application (new or retrofit) requires a careful evaluation of (1) the local power requirements and revenues for power generation, (2) the local meteorological conditions, and (3) the capabilities and costs of different TIC technology options, offered by the various TIC vendors (see [www.turbineinletcooling.org](http://www.turbineinletcooling.org)).

**FIG. 24-65** Mechanical refrigeration TIC systems utilizing chilled water for cooling turbine inlet air, and cooling towers to reject the waste heat into the environment, account for the majority of refrigeration TIC systems sold.

## INTRODUCTION

The selection of materials of construction for the equipment and facilities to produce any and all chemicals is a keystone subject of chemical engineering. The chemical products desired cannot be manufactured without considering the selection of the optimum materials of construction used as the containers for the safe, economical manufacture, and required product quality, i.e., production, handling, transporting, and storage of the products desired. Therefore, within this Section, the selection of materials of construction [for use within the chemical process industries (CPI), and by their consumers] is guided by the general subjects addressed herein,

properties unique to the materials of construction, corrosion of those materials by those chemicals, effect of the products of corrosion upon the product quality, etc. In the cases where specific (and time-sensitive) materials data are needed, that instructive information is to be found in the current reports, technical papers, handbooks (and other texts), etc., of the various other engineering disciplines, e.g., American Society of Metals, ASM; American Society for Testing and Materials, ASTM; American Society of Mechanical Engineers, ASME; National Association Corrosion Engineers, NACE; Society of Plastics Industry, SPI.

## INTRODUCTION\*

The metallurgical extraction of the metals from their ore is the noted chemical reaction of removing the metal from its “stable” compound form (as normally found in nature) to become an “unstable,” artificial form (as used by industry to make tools, containers, equipment, etc.). That instability (of those refined metallic compounds) is the desire of

those metals to return to their (original) more stable, natural state. This is, in effect, the (oversimplified) explanation of the corrosion of artificial metallic things. In its simplest form, iron ore exists in nature as one of several iron oxide (or sulfur, etc.) compounds. For example, when refined iron and/or steel is exposed to oxygenated moisture (recall, this is an electrochemical reaction), thus an electrolyte (e.g. water) is required along with oxygen, and what is formed is iron rust (the same compounds as are the stable state/forms of iron in nature). Those (electrochemical) reactions are called *corrosion of metals*; later it is shown that this very necessary distinction is made to fit that electrochemical definition; i.e., only metals *corrode*, whereas nonmetallic materials may deteriorate (or in other ways be destroyed or weakened), but not corroded.

When a metallic material of construction (MOC) is selected to contain, transport, and/or to be exposed to a specific chemical, unless we make a correct, viable, and optimum MOC selection, the life expectancy of those facilities, in a given chemical exposure, can be very short. For the inexperienced in this field, the direct capital costs of the MOC facet of the production of chemicals, the funds spent to maintain these facilities (sometimes several times those initial capital costs), the indirect costs that are associated with outages and loss of production, off-quality product (because of equipment and facility maintenance) as well as from contamination of the product, etc., are many times not even considered, let alone used as one of the major criteria in the selection of that MOC as well as its costs to keep the plant running, i.e., a much overlooked cost figure in the CPI. To emphasize the magnitude and overall economic nature of the direct and indirect (nonproductive) costs/losses that result from the action of corrosion of our metallic facilities, equipment, and the infrastructures, within the United States, Congress has mandated that a survey of the costs of corrosion in the United States be conducted periodically.

The most recent study was conducted by CC Technologies Laboratories, Inc. (circa 1999 to 2001), with support by the Federal Highways Administration and the National Association of Corrosion Engineers, International. The results of the study show that the (estimated) total annual direct costs of corrosion in the United States are \$276 billion, i.e., about 3.1 percent of the U.S. Gross Domestic Product (GDP). That

\*Includes information excerpted from papers noted, with the courtesy of ASM, ASTM, and NACE International.

loss to the economy is greater than the GDP of many smaller countries. For example, almost 50 percent of the U.S. steel production is used to compensate for the loss of corroded manufacturing facilities and products; in turn, the petroleum industry spends upward of \$2 million per day due to the corrosion of underground installations, e.g., tanks, piping, and other structures. None of those figures include any indirect costs resulting from corrosion, found to be about as great as the direct costs shown in the study. These indirect costs are difficult to come by because they include losses to the customers and other users and result in a major loss to the overall economy itself due to loss of productivity; at the same time, there are innumerable losses that can only be guessed at. In addition to those economic losses, other factors, e.g., health and safety, are without a method to quantify. The details of this study can be found in the supplement to the July 2002 NACE journal *Materials Performance*, "Corrosion Costs and Preventive Strategies, in the United States," which summarized the FHWA-funded study. It is interesting to note that a similar government-mandated study reported a decade ago in the Seventh Edition of *Perry's Chemical Engineers' Handbook* listed that annual loss at \$300 billion; the earlier evaluation technique was to numerically update (extrapolate) the results of earlier studies, i.e., not nearly so sophisticated as was this 2000 study. A study (similar to the year 2000 U.S. evaluation) was conducted by Dr. Rajan Bhaskaran, of Tamilnadu, India, who has proposed a technique to quantify the global costs of corrosion, both direct and indirect. That global study was published by the American Society for Metals, ASM, in the *ASM Handbook*, vol. 13B, December 2005.

The editors of the "Materials of Construction" section expect that the reader knows little about corrosion; thus, an attempt has been made to present information to engineers of all backgrounds.

*A word of caution:* Metals, materials in general, chemicals used to study metals in the laboratory, chemicals used for corrosion protection, and essentially any chemicals should be (1) used in compliance with all applicable codes, laws, and regulations; (2) handled by trained and experienced individuals in keeping with workmanlike environmental and safety standards; and (3) disposed only using allowable methods and in allowable quantities.

## FLUID CORROSION

In the selection of materials of construction for a particular fluid system, it is important first to take into consideration the **characteristics of the system**, giving special attention to all factors that may influence corrosion. Since these factors would be peculiar to a particular system, it is impractical to attempt to offer a set of hard and fast rules that would cover all situations.

The **materials** from which the system is to be fabricated are the second important consideration; therefore, knowledge of the characteristics and general behavior of materials when exposed to certain environments is essential.

In the absence of factual corrosion information for a particular set of fluid conditions, a reasonably good selection would be possible from data based on the resistance of materials to a very similar environment. These data, however, should be used with considerable reservations. Good practice calls for applying such data for preliminary screening. Materials selected thereby would require further study in the fluid system under consideration.

## FLUID CORROSION: GENERAL

**Introduction** Corrosion is the destructive attack upon a metal by its environment or with sufficient damage to its properties, such that it can no longer meet the design criteria specified. Not all metals and their alloys react in a consistent manner when in contact with corrosive fluids. One of the common intermediate reactions of a metal surface is achieved with oxygen, and those reactions are variable and complex. Oxygen can sometimes function as an electron acceptor and cause cathodic depolarization by removing the "protective" film of hydrogen from the cathodic area. In other cases, oxygen can form protective oxide films. The long-term stability of these films also varies: some are soluble in the environment, others form more stable and inert passive films. Electrochemically, a metal surface is in the *active*

state (the anode), i.e., in which the metal tends to corrode, or is being corroded. When a metal is *passive*, it is in the cathodic state, i.e., the state of a metal when its behavior is much more noble (resists corrosion) than its position in the emf series would predict. Passivity is the phenomenon of an (electrochemically) unstable metal in a given electrolyte remaining observably unchanged for an extended period of time.

**Metallic Materials** Pure metals and their alloys tend to enter into **chemical** union with the elements of a corrosive medium to form stable compounds similar to those found in nature. When metal loss occurs in this way, the compound formed is referred to as the **corrosion product** and the metal surface is spoken of as being **corroded**.

Corrosion is a complex phenomenon that may take any one or more of several forms. It is usually confined to the metal surface, and this is called **general corrosion**. But it sometimes occurs along defective and/or weak grain boundaries or other lines of weakness because of a difference in resistance to attack or local electrolytic action.

In most aqueous systems, the corrosion reaction is divided into an anodic portion and a cathodic portion, occurring simultaneously at discrete points on metallic surfaces. Flow of electricity from the anodic to the cathodic areas may be generated by local cells set up either on a single metallic surface (because of local point-to-point differences on the surface) or between dissimilar metals.

**Nonmetallics** As stated, corrosion of metals applies specifically to chemical or electrochemical attack. The deterioration of plastics and other nonmetallic materials, which are susceptible to swelling, crazing, cracking, softening, and so on, is essentially **physiochemical** rather than electrochemical in nature. Nonmetallic materials can either be rapidly deteriorated when exposed to a particular environment or, at the other extreme, be practically unaffected. Under some conditions, a nonmetallic may show evidence of gradual deterioration. However, it is seldom possible to evaluate its chemical resistance by measurements of weight loss alone, as is most generally done for metals.

## FLUID CORROSION: LOCALIZED

**Pitting Corrosion** Pitting is a form of corrosion that develops in highly localized areas on the metal surface. This results in the development of cavities or pits. They may range from deep cavities of small diameter to relatively shallow depressions. Pitting examples: aluminum and stainless alloys in aqueous solutions containing chloride. **Inhibitors** are sometimes helpful in preventing pitting.

**Crevice Corrosion** Crevice corrosion occurs within or adjacent to a crevice formed by contact with another piece of the same or another metal or with a nonmetallic material. When this occurs, the intensity of attack is usually more severe than on surrounding areas of the same surface.

This form of corrosion can result because of a deficiency of oxygen in the crevice, acidity changes in the crevice, buildup of ions in the crevice, or depletion of an inhibitor.

**Oxygen-Concentration Cell** The oxygen-concentration cell is an electrolytic cell in which the driving force to cause corrosion results from a difference in the amount of oxygen in solution at one point as compared with another. Corrosion is accelerated where the oxygen concentration is least, for example, in a stuffing box or under gaskets. This form of corrosion will also occur under solid substances that may be deposited on a metal surface and thus shield it from ready access to oxygen. Redesign or change in mechanical conditions must be used to overcome this situation.

**Galvanic Corrosion** Galvanic corrosion is the corrosion rate above normal that is associated with the flow of current to a less active metal (cathode) in contact with a more active metal (anode) in the same environment. Table 25-1 shows the **galvanic** series of various metals. It should be used with caution, since exceptions to this series in actual use are possible. However, as a general rule, when dissimilar metals are used in contact with each other and are exposed to an electrically conducting solution, combinations of metals that are as close as possible in the galvanic series should be chosen. Coupling two metals widely separated in this series generally will produce accelerated attack on the more active metal. Often, however, protective oxide films and other effects will tend to reduce galvanic corrosion. Galvanic corrosion can, of course, be prevented by **insulating** the metals from

TABLE 25-1 Practical Galvanic Series of Metals and Alloys

This is a composite galvanic series from a variety of sources and is not necessarily representative of any one particular environment.

each other. For example, when plates are bolted together, specially designed plastic washers can be used.

Potential differences leading to galvanic-type cells can also be set up on a single metal by differences in temperature, velocity, or concentration (see subsection "Crevice Corrosion").

**Area effects** in galvanic corrosion are very important. An unfavorable area ratio is a large cathode and a small anode. Corrosion of the anode may be 100 to 1,000 times greater than if the two areas were the same. This is the reason why stainless steels are susceptible to rapid pitting in some environments. Steel rivets in a copper plate will corrode much more severely than a steel plate with copper rivets.

**Intergranular Corrosion** Selective corrosion in the grain boundaries of a metal or alloy without appreciable attack on the grains or crystals themselves is called intergranular corrosion. When severe, this attack causes a loss of strength and ductility out of proportion to the amount of metal actually destroyed by corrosion.

The **austenitic stainless steels** that are not stabilized or that are not of the extra-low-carbon types, when heated in the temperature range of 450 to 843°C (850 to 1,550°F), have chromium-rich compounds (chromium carbides) precipitated in the grain boundaries. This causes grain-boundary impoverishment of chromium and makes the affected metal susceptible to intergranular corrosion in many environments. Hot nitric acid is one environment which causes severe

intergranular corrosion of austenitic stainless steels with grain-boundary precipitation. Austenitic stainless steels stabilized with niobium (columbium) or titanium to decrease carbide formation or containing less than 0.03 percent carbon are normally not susceptible to grain-boundary deterioration when heated in the given temperature range. Unstabilized austenitic stainless steels or types with normal carbon content, to be immune to intergranular corrosion, should be given a solution anneal. This consists of heating to 1,090°C (2,000°F), holding at this temperature for a minimum of 1 h/in of thickness, followed by rapidly quenching in water (or, if impractical because of large size, rapidly cooling with an air-water spray).

**Stress-Corrosion Cracking** Corrosion can be accelerated by stress, either residual internal stress in the metal or externally applied stress. Residual stresses are produced by deformation during fabrication, by unequal cooling from high temperature, and by internal structural rearrangements involving volume change. Stresses induced by rivets and bolts and by press and shrink fits can also be classified as residual stresses. Tensile stresses at the surface, usually of a magnitude equal to the yield stress, are necessary to produce stress-corrosion cracking. However, failures of this kind have been known to occur at lower stresses.

Virtually every alloy system has its specific environment conditions which will produce stress-corrosion cracking, and the time of exposure required to produce failure will vary from minutes to years. Typical examples include cracking of cold-formed brass in ammonia environments, cracking of austenitic stainless steels in the presence of chlorides, cracking of Monel in hydrofluosilicic acid, and caustic embrittlement cracking of steel in caustic solutions.

This form of corrosion can be prevented in some instances by eliminating high stresses. Stresses developed during fabrication, particularly during welding, are frequently the main source of trouble. Of course, temperature and concentration are also important factors in this type of attack.

Presence of **chlorides** does not generally cause cracking of austenitic stainless steels when temperatures are below about 50°C (120°F). However, when temperatures are high enough to concentrate chlorides on the stainless surface, cracking may occur when the chloride concentration in the surrounding media is a few parts per million. Typical examples are cracking of heat-exchanger tubes at the crevices in rolled joints and under scale formed in the vapor space below the top tube sheet in vertical heat exchangers. The cracking of stainless steel under insulation is caused when chloride-containing water is concentrated on the hot surfaces. The chlorides may be leached from the insulation or may be present in the water when it enters the insulation. Improved design and maintenance of insulation weatherproofing, coating of the metal prior to the installation of insulation, and use of chloride-free insulation are all steps which will help to reduce (but not eliminate) this problem.

Serious stress-corrosion-cracking failures have occurred when chloride-containing hydrotest water was not promptly removed from stainless-steel systems. Use of potable-quality water and complete draining after test comprise the most reliable solution to this problem. Use of chloride-free water is also helpful, especially when prompt drainage is not feasible.

In handling caustic, as-welded steel can be used without developing caustic-embrittlement cracking if the temperature is below 50°C (120°F). If the temperature is higher and particularly if the concentration is above about 30 percent, cracking at and adjacent to non-stress-relieved welds frequently occurs.

**Liquid-Metal Corrosion** Liquid metals can also cause corrosion failures. The most damaging are liquid metals which penetrate the metal along grain boundaries to cause catastrophic failure. Examples include mercury attack on aluminum alloys and attack of stainless steels by molten zinc or aluminum. A fairly common problem occurs when galvanized-structural-steel attachments are welded to stainless piping or equipment. In such cases it is mandatory to remove the galvanizing completely from the area which will be heated above 260°C (500°F).

**Erosion** Erosion of metal is the **mechanical** destruction of a metal by abrasion or attrition caused by the flow of liquid or gas (with or without suspended solids); **in no manner is this metal loss an electrochemical corrosion mechanism** (see Velocity Accelerated

Corrosion, below). The use of harder materials and changes in velocity or environment are methods employed to prevent erosion attack.

**Velocity Accelerated Corrosion** This phenomenon is sometimes (**incorrectly**) referred to as erosion-corrosion or velocity corrosion. It occurs when damage is accelerated by the **fluid exceeding its critical flow velocity at that temperature, in that metal. For that system, this is an undesirable** removal of corrosion products (such as oxides) which would otherwise tend to stifle the corrosion reaction.

**Corrosion Fatigue** Corrosion fatigue is a reduction by corrosion of the ability of a metal to withstand **cyclic or repeated stresses**. The surface of the metal plays an important role in this form of damage, as it will be the most highly stressed and at the same time subject to attack by the corrosive media. Corrosion of the metal surface will lower fatigue resistance, and stressing of the surface will tend to accelerate corrosion.

Under cyclic or repeated stress conditions, rupture of protective oxide films that prevent corrosion takes place at a greater rate than that at which new protective films can be formed. Such a situation frequently results in formation of anodic areas at the points of rupture; these produce pits that serve as stress-concentration points for the origin of cracks that cause ultimate failure.

**Cavitation** Formation of transient voids or vacuum bubbles in a liquid stream passing over a surface is called cavitation. This is often encountered around propellers, rudders, and struts and in pumps. When these bubbles collapse on a metal surface, there is a severe impact or explosive effect that can cause considerable mechanical damage, and corrosion can be greatly accelerated because of the destruction of protective films. Redesign or a more resistant metal is generally required to avoid this problem.

**Fretting Corrosion** This attack occurs when metals slide over each other and cause mechanical damage to one or both. In such a case, frictional heat oxidizes the metal and this oxide then wears away; or the mechanical removal of protective oxides results in exposure of fresh surface for corrosive attack. Fretting corrosion is minimized by using harder materials, minimizing friction (via lubrication), or designing equipment so that no relative movement of parts takes place.

**Hydrogen Attack** At elevated temperatures and significant hydrogen partial pressures, hydrogen will penetrate carbon steel, reacting with the carbon in the steel to form methane. The pressure generated causes a loss of ductility (hydrogen embrittlement) and failure by cracking or blistering of the steel. The removal of the carbon from the steel (decarburization) results in decreased strength. Resistance to this type of attack is improved by alloying with molybdenum or chromium. Accepted limits for the use of carbon and low-alloy steels are shown in the so-called Nelson curves; see American Petroleum Institute (API) Publication 941, *Steels for Hydrogen Service at Elevated Temperatures and Pressures in Petroleum Refineries and Petrochemical Plants*.

Hydrogen damage can also result from hydrogen generated in electrochemical corrosion reactions. This phenomenon is most commonly observed in solutions of specific weak acids. H<sub>2</sub>S and HCN are the most common, although other acids can cause the problem. The atomic hydrogen formed on the metal surface by the corrosion reaction diffuses into the metal and forms molecular hydrogen at microvoids in the metal. The result is failure by embrittlement, cracking, and blistering.

## FLUID CORROSION: STRUCTURAL

**Graphitic Corrosion** Graphitic corrosion usually involves **gray cast iron** in which metallic iron is converted into corrosion products, leaving a residue of intact graphite mixed with iron-corrosion products and other insoluble constituents of cast iron.

When the layer of graphite and corrosion products is impervious to the solution, corrosion will cease or slow down. If the layer is porous, corrosion will progress by galvanic behavior between graphite and iron. The rate of this attack will be approximately that for the maximum penetration of steel by pitting. The layer of graphite formed may also be effective in reducing the galvanic action between cast iron and more noble alloys such as bronze used for valve trim and impellers in pumps.

**Low-alloy cast irons** frequently demonstrate a superior resistance to graphitic corrosion, apparently because of their denser structure and the development of more compact and more protective graphitic coatings. Highly alloyed **austenitic cast irons** show considerable superiority over gray cast irons to graphitic corrosion because of the more noble potential of the austenitic matrix plus more protective graphitic coatings.

**Carbon steels** heated for prolonged periods at temperatures above 455°C (850°F) may be subject to the segregation of carbon, which is transformed into graphite. When this occurs, the structural strength of the steel will be affected. Killed steels or low-alloy steels of chromium and molybdenum or chromium and nickel should be considered for elevated-temperature services.

**Parting, or Dealloying, Corrosion\*** This type of corrosion occurs when only one component of an alloy is selectively removed by corrosion or leaching. The most common type of parting or dealloying is dezincification of a copper zinc brass, i.e., such as the parting of zinc from the brass, leaving a copper residue (see below). Various kinds of selective dissolution have been named after the alloy family that has been affected, usually on the basis of the dissolved metal (except in the case of graphitic corrosion; see "Graphitization" above). Similar selective corrosion also may lead to terms such as *denickelification* and *demolybdenumization*, etc. The element removed is always anodic to the alloy matrix. While the color of the damaged alloy may change, there is no [apparent (macro)] evidence of a loss of metal, shape, or dimensions and generally, even the original surface and contour remains. That said, the affected metal becomes lighter and porous and loses its original mechanical properties.

**Dezincification** Dezincification is corrosion of a brass alloy containing zinc in which the principal product of corrosion is metallic copper. This may occur as plugs filling pits (plug type) or as continuous layers surrounding an unattacked core of brass (general type). The mechanism may involve overall corrosion of the alloy followed by reposition of the copper from the corrosion products or selective corrosion of zinc or a high-zinc phase to leave copper residue. This form of corrosion is commonly encountered in brasses that contain more than 15 percent zinc and can be either eliminated or reduced by the addition of small amounts of **arsenic, antimony, or phosphorus** to the alloy.

**Microbiologically Influenced Corrosion (MIC)<sup>†</sup>** This brief review is presented from a practical, industrial point of view. Subjects include materials selection, operational, and other considerations that real-world facilities managers and engineers and others charged with preventing and controlling corrosion need to take into account to prevent or minimize potential MIC problems. As a result of active research by investigators worldwide in the last 30 years, MIC is now recognized as a problem in most industries, including the petroleum production and transportation, gas pipeline, water distribution, fire protection, storage tank, nuclear and fossil power, chemical process, and pulp and paper industries.

A seminal summary of the evolutionary study leading to the discovery of a unique type of MIC, the final identification of the mechanism, and its control can be found in Daniel H. Pope, "State-of-the-Art Report on Monitoring, Prevention and Mitigation of Microbiologically Influenced Corrosion in the Natural Gas Industry," Report No. 96-0488, Gas Research Institute.

*Microbiologically influenced corrosion* is defined by the National Association of Corrosion Engineers as any form of corrosion that is influenced by the presence and/or activities of microorganisms. Although MIC appears to many humans to be a new phenomenon, it is not new to the microbes themselves. Microbial transformation of metals in their elemental and various mineral forms has been an essential part of material cycling on earth for billions of years. Some forms of metals such as reduced iron and manganese serve as energy sources for microbes, while oxidized forms of some metals can substitute for

\*Additional reference material came from "Dealloying Corrosion Basics," *Materials Performance*, vol. 33, no. 5, p. 62, May 2006, adapted by NACE from *Corrosion Basics—An Introduction*, by L. S. Van Dellen (ed.), NACE, Houston, Tex., 1984, pp. 105–107.

oxygen as electron acceptors in microbial metabolism. Other metals are transformed from one physical and chemical state to another as a result of exposure to environments created by microbes performing their normal metabolic activities. Of special importance are microbial activities which create oxidizing, reducing, acidic, or other conditions under which one form of a metal is chemically transformed to another. It is important to understand that the microbes are simply doing "what comes naturally." Unfortunately when microbial communities perform their natural activities on metals and alloys which would rather be in less organized and more natural states (minerals), corrosion often results.

Most microbes in the real world, especially those associated with surfaces, live in communities consisting of many different types of microbes, each of which can perform a variety of biochemical reactions. This allows microbial communities to perform a large variety of different reactions and processes which would be impossible for any single type of microbe to accomplish alone. Thus, e.g., even in overtly aerobic environments, microbial communities and the metal surfaces underlying them can have zones in which little or no oxygen is present. The result is that aerobic, anaerobic, fermentative, and other metabolic-type reactions can *all* occur in various locations within a microbial community. When these conditions are created on an underlying metal surface, then physical, chemical, and electrochemical conditions are created in which a variety of corrosion mechanisms can be induced, inhibited, or changed in their forms or rates. These include oxygen concentration cell corrosion, ion concentration cell corrosion, under-deposit acid attack corrosion, crevice corrosion, and under-deposit pitting corrosion. Note, however, that all these corrosion processes are electrochemical.

Most practicing engineers are not, and do not need to become, experts in the details of MIC. What is needed is to recognize that MIC-type corrosion can affect almost any metal or alloy exposed to MIC-related microbes in untreated waters, and therefore many types of equipment and structures are at risk. It is critical that MIC be properly diagnosed, or else mitigation methods designed to control MIC may be misapplied, resulting in failure to control the corrosion problem, unnecessary cost, and unnecessary concerns about exposure of the environment and personnel to potentially toxic biological control agents. Fortunately better tools are now available for monitoring and detection of MIC (see the later subsections on laboratory and field corrosion testing, both of which address the subject of MIC). Microbiological, chemical, metallurgical, and operational information is all useful in the diagnosis of MIC and should be used if available. All types of information should conform to the diagnosis of MIC—the data should not be in conflict with one another.

Bacteria, as a group, can grow over very wide ranges of pH, temperature, and pressure. They can be obligate aerobes (require oxygen to survive and grow), microaerophiles (require low oxygen concentrations), facultative anaerobes (prefer aerobic conditions but will live under anaerobic conditions), or obligate anaerobes (will grow only under conditions where oxygen is absent). It should be emphasized that most anaerobes will survive aerobic conditions for quite a while, and the same is true for aerobes in anaerobic conditions. Most MIC-related bacteria are heterotrophic and as a group may use as food almost any available organic carbon molecules, from simple alcohols or sugars to phenols and petroleum products, to wood or various other complex polymers. Unfortunately some MIC-related microbial communities can also use some biocides and corrosion inhibitors as food stuffs. Other microbes are autotrophs (fix CO<sub>2</sub>, as do plants). Some microbes use inorganic elements or ions (e.g., NH<sub>3</sub>, NO<sub>2</sub>, CH<sub>3</sub>, H<sub>2</sub>, S, H<sub>2</sub>S, Fe<sup>2+</sup>, Mn<sup>2+</sup>, etc.), as sources of energy. Although microbes can exist in extreme conditions, most require a limited number of organic molecules, moderate temperatures, moist environments, and near-neutral bulk environmental pH.

**Buried Structures** There has been no dramatic improvement in the protection of buried structures against MIC over the last several decades. Experience has been that coating systems, by themselves, do not provide adequate protection for a buried structure over the years; for best results, a properly designed and maintained cathodic protection (CP) system *must* be used in conjunction with a protective coating (regardless of the quality of the coating, as applied) to control

MIC and other forms of corrosion. Adequate levels of CP (the level of CP required is dependent on local environmental conditions, e.g., soil pH, moisture, presence of sealing chemicals) provide caustic environment protection at the holes (holidays) in the coating that are sure to develop with time due to one cause or another. The elevated pH (>10.0) produced by adequate CP discourages microbial growth and metabolism and tends to neutralize acids which are produced as a result of microbial metabolism and corrosion processes. Proper levels of CP, if applied uniformly to the metal surface, also raise the electrochemical potential of the steel to levels at which it does not want to corrode. Areas of metal surface under disbonded coating, under preexisting deposits (including those formed due to microbial actions), and other materials acting to insulate areas of the pipe and "holidays" from achieving adequate CP will often not be protected and may suffer very rapid under-deposit, crevice, and pitting corrosion. In short, adequate CP must be applied *before* MIC communities have become established under disbonded coating or in holidays. Application of CP after MIC processes and sites have been established may *not* stop MIC from occurring.

The user of cathodic protection must also consider the material being protected with regard to caustic cracking; a cathodic potential driven to the negative extreme of -0.95 V for microbiological protection purposes can cause caustic cracking of a steel structure. The benefits and risks of cathodic protection must be weighed for each material and each application.

Backfilling with limestone or other alkaline material is an added step to protect buried structures from microbiological damage. Providing adequate drainage to produce a dry environment both above and below ground in the area of the buried structure will also reduce the risk of this type of damage.

Corrosion of buried structures has been blamed on the sulfate-reducing bacteria (SRB) for well over a century. It was easy to blame the SRB for the corrosion as they smelled very bad (rotten egg smell). It is now known that SRB are one component of the MIC communities required to get corrosion of most buried structures.

**Waters** Water is required at a MIC "site" to allow microbial growth and corrosion reactions to occur. Most surfaces exposed to natural or industrial environments have large numbers of potential MIC-related microbes associated with them. Most natural and industrial waters (even "ultrapure," distilled, or condensate waters) contain large numbers of microbes. Since the potential to participate in MIC is a property of a large percentage of known microbes, it is not surprising that the potential for developing MIC is present in most natural and industrial environments on earth. Many industries assumed that they were protected against MIC as they used ultrapure waters, in which they assumed microbes were kept in check by the lack of organic food sources for the microbes. However, as several early cases of MIC in the chemical process industry demonstrated, MIC was capable of causing rapid and severe damage to stainless steel welds which had come into contact only with potable drinking water. Since that time, numerous cases of MIC have been reported in breweries; pharmaceutical, nuclear, and computer chip manufacturing; and other industries using highly purified waters. Many other cases of MIC have been documented in metals in contact with "normally treated" municipal waters.

**Hydrostatic Testing Waters** Microbes capable of causing MIC are present in most waters (even those treated by water purveyors to kill pathogens) used for hydrostatic (safety) testing of process equipment and for process batch waters. Use of these waters has resulted in a large number of documented cases of MIC in a variety of industries. Guidelines for treatment and use of hydrotest waters have been adopted by several industrial and government organizations in an effort to prevent this damage. Generally, good results have been reported for those who have followed this practice. Unfortunately, this can be an expensive undertaking where the need cannot be totally quantified (and thus justified to management). Cost-cutting practices which either ignore these guidelines or follow an adulteration of proven precautions can lead to major MIC damage to equipment and process facilities.

Untreated natural freshwaters from wells, lakes, or rivers commonly contain high levels of MIC-related microbes. These waters should not be used without appropriate treatment. Most potable

waters are treated sufficiently to prevent humans from having contact with waterborne pathogenic bacteria, but *are not* treated with sufficient disinfectant to kill all MIC-related microbes in the water.

They should not be used for hydrotesting or other such activities without appropriate treatment. Biocide treatment of hydrotest waters should be very carefully chosen to make sure that the chemicals are compatible with the materials in the system to be tested and to prevent water disposal problems (most organic biocides cause disposal problems). Use of inexpensive, effective, and relatively accepted biocides such as chlorine, ozone, hydrogen peroxide and iodine should be considered where compatibility with materials and other considerations permit. (For example, use of relatively low levels of iodine in hydrotest waters might be acceptable in steel pipes while stainless steels are much better tested using waters treated with nonhalogen, but oxidizing biocides such as hydrogen peroxide.) Obviously, chlorine must be used only with great care because of the extensive damage it will cause to the 300-series austenitic stainless steels. In all cases, as soon as the test is over, the water *must be completely* drained and the system thoroughly dried so that no vestiges of water are allowed to be trapped in occluded areas. The literature abounds with instructions as to the proper manner in which to accomplish the necessary and MIC-safe testing procedures. Engineering personnel planning these test operations should avail themselves of that knowledge.

**Materials of Construction** MIC processes are those processes by which manufactured materials deteriorate through the presence and activities of microbes. These processes can be either direct or indirect. Microbial biodeterioration of a great many materials (including concretes, glasses, metals and their alloys, and plastics) occurs by diverse mechanisms and usually involves a complex community consisting of many different species of microbes.

The corrosion engineers' solution to corrosion problems sometimes includes upgrading the materials of construction. This is a natural approach, and since microbiological corrosion most often results in crevice or under-deposit attack, this option is logical. Unfortunately, with MIC, the use of more materials traditionally thought to be more corrosion-resistant can lead to disastrous consequences. The occurrence and severity of any particular case of MIC are dependent upon the types of microbes involved, the local physical environment (temperature, water flow rates, etc.) and chemical environment (pH, hardness, alkalinity, salinity, etc.) and the type of metals or alloys involved. As an example, an upgrade from type 304 to 316 stainless steel does not always help. Kobrin reported biological corrosion of delta ferrite stringers in weld metal. Obviously, this upgrade was futile; type 316 stainless steel can contain as much as or more delta ferrite than does type 304. Kobrin also reported MIC of nickel, nickel-copper alloy 400, and nickel-molybdenum alloy B heat-exchanger tubes. Although the alloy 400 and alloy B were not pitted as severely as the nickel tubes, the use of higher alloys did not solve the corrosion problem.

In the past, copper was believed to be toxic to *most* microbiological species. Although this may be true in a test tube under laboratory conditions, it is not generally true in the real world. In this real world, microbial communities excrete slime layers which tend to sequester the copper ions and prevent their contact with the actual microbial cells, thus preventing the copper from killing the microbes. Many cases of MIC in copper and copper alloys have been documented, especially of heat-exchange tubes, potable water, and fire protection system piping.

At this stage of knowledge about MIC, only titanium, zirconium, and tantalum appear to be immune to microbiological damage.

## FACTORS INFLUENCING CORROSION

**Solution pH** The corrosion rate of most metals is affected by pH. The relationship tends to follow one of three general patterns:

1. Acid-soluble metals such as iron have a relationship as shown in Fig. 25-1a. In the middle pH range ( $\approx 4$  to 10), the corrosion rate is controlled by the rate of transport of oxidizer (usually dissolved  $O_2$ ) to the metal surface. Iron is weakly amphoteric. At very high temperatures such as those encountered in boilers, the corrosion rate increases with increasing basicity, as shown by the dashed line.

(a)

(b)

(c)

**FIG. 25-1** Effect of pH on the corrosion rate. (a) Iron. (b) Amphoteric metals (aluminum, zinc). (c) Noble metals.

2. Amphoteric metals such as aluminum and zinc have a relationship as shown in Fig. 25-1b. These metals dissolve rapidly in either acidic or basic solutions.

3. Noble metals such as gold and platinum are not appreciably affected by pH, as shown in Fig. 25-1c.

**Oxidizing Agents** In some corrosion processes, such as the solution of zinc in hydrochloric acid, hydrogen may evolve as a gas. In others, such as the relatively slow solution of copper in sodium chloride, the removal of hydrogen, which must occur so that corrosion may proceed, is effected by a reaction between hydrogen and some oxidizing chemical such as oxygen to form water. Because of the high rates of corrosion which usually accompany hydrogen evolution, metals are rarely used in solutions from which they evolve hydrogen at an appreciable rate. As a result, most of the corrosion observed in practice occurs under conditions in which the oxidation of hydrogen to form water is a necessary part of the corrosion process. For this reason, oxidizing agents are often powerful accelerators of corrosion, and in many cases the **oxidizing power of a solution** is its most important single property insofar as corrosion is concerned.

Oxidizing agents that accelerate the corrosion of some materials may also retard corrosion of others through the formation on their surface

of oxides or layers of adsorbed oxygen which make them more resistant to chemical attack. This property of chromium is responsible for the principal corrosion-resisting characteristics of the stainless steels.

It follows, then, that oxidizing substances, such as dissolved air, may accelerate the corrosion of one class of materials and retard the corrosion of another class. In the latter case, the behavior of the material usually represents a balance between the power of oxidizing compounds to preserve a protective film and their tendency to accelerate corrosion when the agencies responsible for protective-film breakdown are able to destroy the films.

**Temperature** The rate of corrosion tends to increase with rising temperature. Temperature also has a secondary effect through its influence on the solubility of air (oxygen), which is the most common oxidizing substance influencing corrosion. In addition, temperature has specific effects when a temperature change causes phase changes which introduce a corrosive second phase. Examples include condensation systems and systems involving organics saturated with water.

**Velocity** Most metals and alloys are protected from corrosion, not by *nobility* [a metal's inherent resistance to enter into an electrochemical reaction with that environment, e.g., the (intrinsic) inertness of gold to (almost) everything but aqua regia], but by the formation of a *protective film* on the surface. In the examples of film-forming protective cases, the film has similar, but more limiting, specific assignment of that exemplary-type resistance to the exposed environment (not nearly so broad-based as noted in the case of gold). Velocity-accelerated corrosion is the accelerated or increased rate of deterioration or attack on a metal surface because of relative movement between a corrosive fluid and the metal surface, i.e., the instability (velocity sensitivity) of that protective film.

An increase in the velocity of relative movement between a corrosive solution and a metallic surface frequently tends to accelerate corrosion. This effect is due to the higher rate at which the corrosive chemicals, including oxidizing substances (air), are brought to the corroding surface and to the higher rate at which corrosion products, which might otherwise accumulate and stifle corrosion, are carried away. The higher the velocity, the thinner will be the films which corroding substances must penetrate and through which soluble corrosion products must diffuse.

Whenever corrosion resistance results from the formation of layers of insoluble corrosion products on the metallic surface, the effect of high velocity may be to prevent their normal formation, to remove them after they have been formed, and/or to preclude their reformation. All metals that are protected by a film are sensitive to what is referred to as its *critical velocity*; i.e., the velocity at which those conditions occur is referred to as the *critical velocity* of that chemistry/temperature/velocity environmental corrosion mechanism. When the critical velocity of that specific system is exceeded, that effect allows corrosion to proceed unhindered. This occurs frequently in small-diameter tubes or pipes through which corrosive liquids may be circulated at high velocities (e.g., condenser and evaporator tubes), in the vicinity of bends in pipelines, and on propellers, agitators, and centrifugal pumps. Similar effects are associated with cavitation and mechanical erosion.

**Films** Once corrosion has started, its further progress very often is controlled by the nature of films, such as passive films, that may form or accumulate on the metallic surface. The classical example is the thin **oxide film** that forms on stainless steels.

Insoluble corrosion products may be completely impervious to the corroding liquid and, therefore, completely protective; or they may be quite permeable and allow local or general corrosion to proceed unhindered. Films that are nonuniform or discontinuous may tend to localize corrosion in particular areas or to induce accelerated corrosion at certain points by initiating electrolytic effects of the concentration-cell type. Films may tend to retain or absorb moisture and thus, by delaying the time of drying, increase the extent of corrosion resulting from exposure to the atmosphere or to corrosive vapors.

It is agreed generally that the characteristics of the **rust films** that form on steels determine their resistance to atmospheric corrosion. The rust films that form on low-alloy steels are more protective than those that form on unalloyed steel.

In addition to films that originate at least in part in the corroding metal, there are others that originate in the corrosive solution. These

include various salts, such as carbonates and sulfates, which may be precipitated from heated solutions, and insoluble compounds, such as "beer stone," which form on metal surfaces in contact with certain specific products. In addition, there are films of oil and grease that may protect a material from direct contact with corrosive substances. Such oil films may be applied intentionally or may occur naturally, as in the case of metals submerged in sewage or equipment used for the processing of oily substances.

**Other Effects** Stream **concentration** can have important effects on corrosion rates. Unfortunately, corrosion rates are seldom linear with concentration over wide ranges. In equipment such as distillation columns, reactors, and evaporators, concentration can change continuously, making prediction of corrosion rates rather difficult. Concentration is important during plant shutdown; presence of moisture that collects during cooling can turn innocuous chemicals into dangerous corrosives.

As to the effect of time, there is no universal law that governs the reaction for all metals. Some corrosion rates remain constant with time over wide ranges, others slow down with time, and some alloys have increased corrosion rates with respect to time. Situations in which the corrosion rate follows a combination of these paths can develop. Therefore, extrapolation of corrosion data and corrosion rates should be done with utmost caution.

Impurities in a corroder can be good or bad from a corrosion standpoint. An impurity in a stream may act as an inhibitor and actually retard corrosion. However, if this impurity is removed by some process change or improvement, a marked rise in corrosion rates can result. Other impurities, of course, can have very deleterious effects on materials. The chloride ion is a good example; small amounts of chlorides in a process stream can break down the passive oxide film on stainless steels. The effects of impurities are varied and complex. One must be aware of what they are, how much is present, and where they come from before attempting to recommend a particular material of construction.

## HIGH-TEMPERATURE ATTACK

**Physical Properties** The suitability of an alloy for high-temperature service [425 to 1,100°C (800 to 2,000°F)] is dependent upon properties inherent in the alloy composition and upon the conditions of application. Crystal structure, density, thermal conductivity, electrical resistivity, thermal expansivity, structural stability, melting range, and vapor pressure are all physical properties basic to and inherent in individual alloy compositions.

Of usually high relative importance in this group of properties is **expansivity**. A surprisingly large number of metal failures at elevated temperatures are the result of excessive thermal stresses originating from constraint of the metal during heating or cooling. Such constraint in the case of hindered contraction can cause rupturing.

Another important property is alloy **structural stability**. This means freedom from formation of new phases or drastic rearrangement of those originally present within the metal structure as a result of thermal experience. Such changes may have a detrimental effect upon strength or corrosion resistance or both.

**Mechanical Properties** Mechanical properties of wide interest include creep, rupture, short-time strengths, and various forms of ductility, as well as resistance to impact and fatigue stresses. Creep strength and stress rupture are usually of greatest interest to designers of stationary equipment such as vessels and furnaces.

**Corrosion Resistance** Possibly of greater importance than physical and mechanical properties is the ability of an alloy's chemical composition to resist the corrosive action of various hot environments. The forms of high-temperature corrosion which have received the greatest attention are **oxidation** and **scaling**.

Chromium is an essential constituent in alloys to be used above 550°C (1,000°F). It provides a tightly adherent oxide film that materially retards the oxidation process. Silicon is a useful element in imparting oxidation resistance to steel. It will enhance the beneficial effects of chromium. Also, for a given level of chromium, experience has shown oxidation resistance to improve as the nickel content increases.

Aluminum is not commonly used as an alloying element in steel to improve oxidation resistance, as the amount required interferes with

both workability and high-temperature-strength properties. However, the development of high-aluminum surface layers by various methods, including spraying, cementation, and dipping, is a feasible means of improving heat resistance of low-alloy steels.

Contaminants in fuels, especially alkali-metal ions, vanadium, and sulfur compounds, tend to react in the combustion zone to form molten fluxes which dissolve the protective oxide film on stainless steels, allowing oxidation to proceed at a rapid rate. This problem is becoming more common as the high cost and short supply of natural gas and distillate fuel oils force increased usage of residual fuel oils and coal.

## COMBATING CORROSION

**Material Selection** The objective is to select the material which will most economically fulfill the process requirements. The best source of data is well-documented experience in an identical process unit. In the absence of such data, other data sources such as experience in pilot units, corrosion-coupon tests in pilot or bench-scale units, laboratory corrosion-coupon tests in actual process fluids, or corrosion-coupon tests in synthetic solutions must be used. The data from such alternative sources (which are listed in decreasing order of reliability) must be properly evaluated, taking into account the degree to which a given test may fail to reproduce actual conditions in an operating unit. Particular emphasis must be placed on possible composition differences between a static laboratory test and a dynamic plant as well as on trace impurities (chlorides in stainless-steel systems, for example) which may greatly change the corrosiveness of the system. The possibility of severe localized attack (pitting, crevice corrosion, or stress-corrosion cracking) must also be considered.

Permissible **corrosion rates** are an important factor and differ with equipment. Appreciable corrosion can be permitted for tanks and lines if anticipated and allowed for in design thickness, but essentially no corrosion can be permitted in fine-mesh wire screens, orifices, and other items in which small changes in dimensions are critical.

In many instances use of **nonmetallic materials** will prove to be attractive from an economic and performance standpoint. These should be considered when their strength, temperature, and design limitations are satisfactory.

**Proper Design** Design considerations with respect to minimizing corrosion difficulties should include the desirability for free and complete drainage, minimizing crevices, and ease of cleaning and inspection. The installation of baffles, stiffeners, and drain nozzles and the location of valves and pumps should be made so that free drainage will occur and washing can be accomplished without holdup. Means of access for inspection and maintenance should be provided whenever practical. Butt joints should be used whenever possible. If lap joints employing fillet welds are used, the welds should be continuous.

The use of dissimilar metals in contact with each other should generally be minimized, particularly if they are widely separated in their nominal positions in the galvanic series (see Table 28-1a). If they are to be used together, consideration should be given to insulating them from each other or making the anodic material area as large as possible.

Equipment should be supported in such a way that it will not rest in pools of liquid or on damp insulating material. Porous insulation should be weatherproofed or otherwise protected from moisture and spills to avoid contact of the wet material with the equipment. Specifications should be sufficiently comprehensive to ensure that the desired composition or type of material will be used and the right condition of heat treatment and surface finish will be provided. Inspection during fabrication and prior to acceptance is desirable.

**Altering the Environment** Simple changes in environment may make an appreciable difference in the corrosion of metals and should be considered as a means of combating corrosion. **Oxygen** is an important factor, and its removal or addition may cause marked changes in corrosion. The treatment of boiler feedwater to remove oxygen, for instance, greatly reduces the corrosiveness of the water on steel. Inert-gas purging and blanketing of many solutions, particularly acidic media, generally minimize corrosion of copper and nickel-base alloys by minimizing air or oxygen content. Corrosiveness of acid media to stainless alloys, on the other hand, may be reduced by aeration because of the formation of passive oxide films. Reduction in

temperature will almost always be beneficial with respect to reducing corrosion if no corrosive phase changes (condensation, for example) result. Velocity effects vary with the material and the corrosive system. When pH values can be modified, it will generally be beneficial to hold the acid level to a minimum. When acid additions are made in batch processes, it may be beneficial to add them last so as to obtain maximum dilution and minimum acid concentration and exposure time. Alkaline pH values are less critical than acid values with respect to controlling corrosion. Elimination of moisture can and frequently does minimize, if not prevent, corrosion of metals, and this possibility of environmental alteration should always be considered.

**Inhibitors** The use of various substances or inhibitors as additives to corrosive environments to decrease corrosion of metals in the environment is an important means of combating corrosion. This is generally most attractive in closed or recirculating systems in which the annual cost of inhibitor is low. However, it has also proved to be economically attractive for many once-through systems, such as those encountered in petroleum-processing operations. Inhibitors are effective as the result of their controlling influence on the cathode- or anode-area reactions.

Typical examples of inhibitors used for minimizing corrosion of iron and steel in aqueous solutions are the chromates, phosphates, and silicates. Organic sulfide and amine materials are frequently effective in minimizing corrosion of iron and steel in acid solution.

The use of inhibitors is not limited to controlling corrosion of iron and steel. They frequently are effective with stainless steel and other alloy materials. The addition of copper sulfate to dilute sulfuric acid will sometimes control corrosion of stainless steels in hot dilute solutions of this acid, whereas the uninhibited acid causes rapid corrosion.

The effectiveness of a given inhibitor generally increases with an increase in **concentration**, but inhibitors considered practical and economically attractive are used in quantities of less than 0.1 percent by weight.

In some instances the amount of inhibitor present is critical in that a deficiency may result in localized or pitting attack, with the overall results being more destructive than when none of the inhibitor is present. Considerations for the use of inhibitors should therefore include review of experience in similar systems or investigation of requirements and limitations in new systems.

**Cathodic Protection** This electrochemical method of corrosion control has found wide application in the protection of carbon steel underground structures such as pipe lines and tanks from external soil corrosion. It is also widely used in water systems to protect ship hulls, offshore structures, and water-storage tanks.

Two methods of providing cathodic protection for minimizing corrosion of metals are in use today. These are the sacrificial-anode method and the impressed-emf method. Both depend upon making the metal to be protected the cathode in the electrolyte involved.

Examples of the sacrificial-anode method include the use of zinc, magnesium, or aluminum as anodes in electrical contact with the metal to be protected. These may be anodes buried in the ground for protection of underground pipe lines or attachments to the surfaces of equipment such as condenser water boxes or on ship hulls. The current required is generated in this method by corrosion of the sacrificial-anode material. In the case of the impressed emf, the direct current is provided by external sources and is passed through the system by use of essentially nonsacrificial anodes such as carbon, noncorrodible alloys, or platinum buried in the ground or suspended in the electrolyte in the case of aqueous systems.

The requirements with respect to current distribution and anode placement vary with the resistivity of soils or the electrolyte involved.

**Anodic Protection\*** Corrosion of metals, and their alloys, exposed to a given environment requires at least two separate electrochemical (anodic and cathodic) reactions. The corrosion rate is determined at the intersection of these two reactions (see Fig. 25-2a).

Certain metal-electrolyte combinations exhibit active-passive behavior. Carbon steel in concentrated sulfuric acid is a classic example. The surface condition of a metal that has been forced inactive is termed *passive*.

\*Citing of these several publications about anodic protection is noted with the courtesy of NACE International.

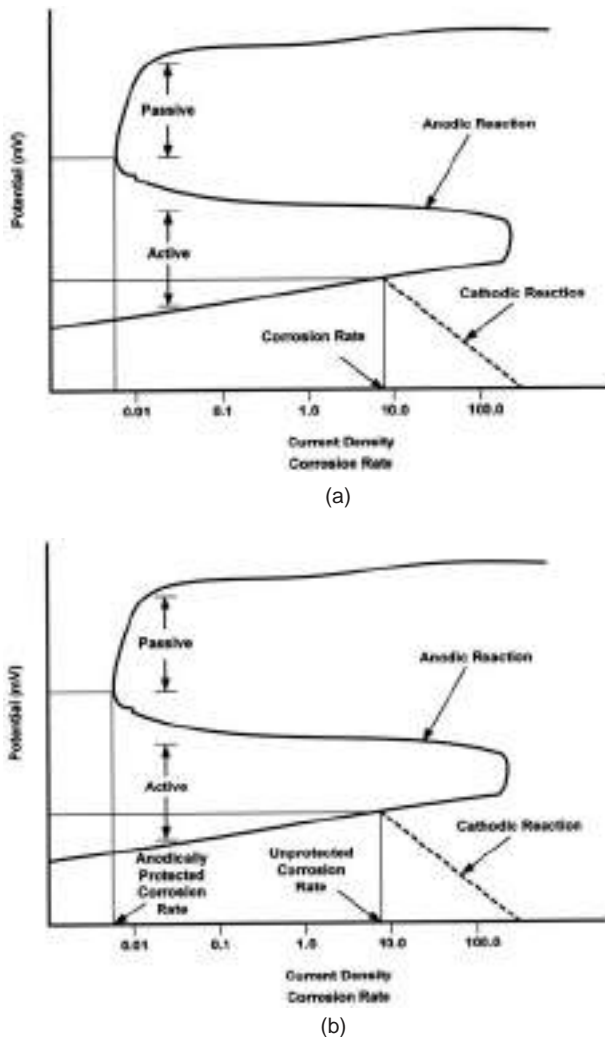

FIG. 25-2 (a) Active-passive behavior. (b) Application of anodic protection.

Anodic protection (AP) is an important method for controlling corrosion when/whereby the corroding (anodic surface) of the metal can be passivated by discharging a current from the surface of that metal, whereby the resulting corrosion product is a protective film. This technique has been known and practiced for nearly 50 years. This electrochemical anodic corrosion protection method relies on an automatic potential controlled current source (potentiostat) to maintain the metal or alloy in a noncorroding (passive) state. See Fig. 25-2b [and Fig. 25-14, the application of the corrosion behavior diagram to select the low-current region (LCR) in the design of an AP system].

The development of improved control instrumentation [e.g., of cathode location (placements), etc.] and many years of proven AP applications in the field have made AP the preferred method of controlling corrosion of uncoated steel equipment handling hot, concentrated sulfuric acid, stainless steel in even hotter exposures, and even steel in nitric acid.

Routinely, AP is used to control corrosion of carbon steel exposed to caustic-sulfide and caustic-aluminate solutions encountered in the pulp and paper and aluminum industries.

With the added benefit of increased product purity (reduced iron contamination), near-zero operational costs speak to AP as the most underapplied corrosion control systems of the ages.

A more recent advancement of AP has come from the application of a controlled cathodic current which can be utilized to shift the corrosion potential back to the passive zone. This (refinement) technique is usually termed the *cathodic potential adjustment protection* (CPAP).

**Coatings and Linings** The use of nonmetallic coatings and lining materials in combination with steel or other materials has and will continue to be an important type of construction for combating corrosion.

**Organic coatings** of many kinds are used as linings in equipment such as tanks, piping, pumping lines, and shipping containers, and they are often an economical means of controlling corrosion, particularly when freedom from metal contamination is the principal objective. One principle that is now generally accepted is that thin nonreinforced paintlike coatings of less than 0.75-mm (0.03-in) thickness should not be used in services for which full protection is required in order to prevent rapid attack of the substrate metal. This is true because most thin coatings contain defects or holidays and can be easily damaged in service, thus leading to early failures due to corrosion of the substrate metal even though the coating material is resistant. Electrical testing for continuity of coating-type linings is always desirable for immersion-service applications in order to detect holiday-type defects in the coating.

The most dependable barrier linings for corrosive services are those which are bonded directly to the substrate and are built up in multiple-layer or laminated effects to thicknesses greater than 2.5 mm (0.10 in). These include flake-glass-reinforced resin systems and elastomeric and plasticized plastic systems. Good surface preparation and thorough inspections of the completed lining, including electrical testing, should be considered as minimum requirements for any lining applications.

Linings of this type are slightly permeable to many liquids. Such permeation, while not damaging to the lining, may cause failure by causing disbonding of the lining owing to pressure buildup between the lining and the steel.

**Ceramic or carbon-brick linings** are frequently used as facing linings over plastic or membrane linings when surface temperatures exceed those which can be handled by the unprotected materials or when the membrane must be protected from mechanical damage. This type of construction permits processing of materials that are too corrosive to be handled in low-cost metal constructions.

**Glass-Lined Steel** By proprietary methods, special glasses can be bonded to steel, providing an impervious liner 1.5 to 2.5 mm (0.060 to 0.100 in) thick. Equipment and piping lined in this manner are routinely used in severely corrosive acid services. The glass lining can be mechanically damaged, and careful attention to details of design, inspection, installation, and maintenance is required to achieve good results with this system.

**Metallic Linings for Severe/Corrosive Environments** The cladding of steel with an alloy is another approach to this problem. There are a number of cladding methods in general use. In one, a sandwich is made of the corrosion-resistant metal and carbon steel by hot rolling to produce a **pressure weld** between the plates.

Another process involves **explosive bonding**. The corrosion-resistant metal is bonded to a steel backing metal by the force generated by properly positioned explosive charges. Relatively thick sections of metal can be bonded by this technique into plates.

In a third process, a **loose liner** is fastened to a carbon steel shell by welds spaced so as to prevent collapse of the liner. A fourth method is **weld overlay**, which involves depositing multiple layers of alloy weld metal to cover the steel surface.

All these methods require careful design and control of fabrication methods to assure success.

**Metallic Linings for Mild Environments** Zinc coatings applied by various means have good corrosion resistance to many atmospheres. Such coatings have been extensively used on steel. Zinc has the advantage of being anodic to steel and therefore will protect exposed areas of steel by electrochemical action.

Steel coated with tin (**tinplate**) is used to make food containers. Tin is more noble than steel; therefore, well-aerated solutions will galvanically accelerate attack of the steel at exposed areas. The comparative absence of air within food containers aids in preserving the tin as well as the food. Also the reversible potential which the tin-iron couple undergoes in organic acids serves to protect exposed steel in food containers.

**Cadmium**, being anodic to steel, behaves quite similarly to zinc in providing corrosion protection when applied as a coating on steel. Tests of zinc and cadmium coatings should be conducted when it becomes necessary to determine the most economical selection for a particular environment.

**Lead** has a good general resistance to various atmospheres. As a coating, it has had its greatest application in the production of terneplate, which is used as a roofing, corncing, and spouting material.

**Aluminum coatings** on steel will perform in a manner similar to zinc coatings. Aluminum has good resistance to many atmospheres; in addition, being anodic to steel, it will galvanically protect exposed areas. Aluminum-coated steel products are quite serviceable under high-temperature conditions, for which good oxidation resistance is required.

#### General Workflow for Minimizing or Controlling Corrosion

In general, the process of reducing and controlling corrosion of metals requires the minimization of the progress of electrochemical deterioration. To accomplish this goal without first changing the selection of material(s), the engineer should generate and follow a punchlist of items the goal of which is to remove essentially any material differences/gradients in the environment of the corroding material(s). Since concentration differences/gradients constitute chemical stress or stress risers that tend to drive corrosion reactions, reducing or eliminating such material differences/gradients constitutes reducing or eliminating stress on the corrosion reaction. Removing the chemical stress places the metal "at rest" with respect to the progress of corrosion.

### CORROSION-TESTING METHODS\*

The primary purpose of materials selection is to provide the optimum equipment for a process application in terms of materials of construction, design, and corrosion-control measures. *Optimum* here means that which comprises the best combination of cost, life, safety, and reliability.

The selection of materials to be used in design dictates a basic understanding of the behavior of materials and the principles that govern such behavior. If proper design of suitable materials of construction is incorporated, the equipment should deteriorate at a uniform and anticipated gradual rate, which will allow scheduled maintenance or replacement at regular intervals. If localized forms of corrosion are characteristic of the combination of materials and environment, the materials engineer should still be able to predict the probable life of equipment, or devise an appropriate inspection schedule to preclude unexpected failures. The concepts of predictive, or at least preventive, maintenance are minimum requirements to proper materials selection. This approach to maintenance is certainly intended to minimize the possibility of unscheduled production shutdowns because of corrosion failures, with their attendant possible financial losses, hazard to personnel and equipment, and resultant environmental pollution.

Chemical processes may involve a complex variety of both inorganic and organic chemicals. Hard and fast rules for selecting the appropriate materials of construction can be given when the composition is known, constant, and free of unsuspected contaminants; when the rel-

evant parameters of temperature, pressure, velocity, and concentration are defined; and when the mechanical and environmental degradation of the material is uniform, that is, free of localized attack. For example, it is relatively simple to select the materials of construction for a regimen of equipment for the storage and handling of cold, concentrated sulfuric acid. On the other hand, the choice of suitable materials for producing phosphoric acid by the digestion of phosphate rock with sulfuric acid is much more difficult because of the diversity in kind and concentration of contaminants, the temperatures of the reactions, and the strength of sulfuric and phosphoric acid used or formed. Probably the best way to approach the study of materials selection is to categorize the types of major chemicals that might be encountered, describe their inherent characteristics, and generalize about the corrosion characteristics of the prominent materials of construction in such environments.

The background information that materials selection is based on is derived from a number of sources. In many cases, information as to the corrosion resistance of a material in a specific environment is not available and must be derived experimentally. It is to this need that the primary remarks of this subsection are addressed.

Unfortunately, there is no standard or preferred way to evaluate an alloy in an environment. While the chemistry of the operating plant environment can sometimes be duplicated in the laboratory, factors of velocity, hot and cold wall effects, crevice, chemical reaction of the fluid during the test, stress levels of the equipment, contamination with products of corrosion, trace impurities, dissolved gases, and so forth also have a controlling effect on the quality of the answer. Then, too, the progress of the corrosion reaction itself varies with time. Notwithstanding, immersion testing remains the most widely used method for selecting materials of construction.

There is no standard or preferred way to carry out a corrosion test; the method must be chosen to suit the purpose of the test. The principal types of tests are, in decreasing order of reliability:

1. Actual operating experience with full-scale plant equipment exposed to the corroding medium.
2. Small-scale plant-equipment experience, under either commercial or pilot-plant conditions.
3. Sample tests in the field. These include coupons, stressed samples, electrical-resistance probes exposed to the plant corroding medium, or samples exposed to the atmosphere, to soils, or to fresh, brackish, or saline waters. Samples for viable microbes involved in MIC must be processed immediately in the field into appropriate growth media.
4. Laboratory tests on samples exposed to "actual" plant liquids or simulated environments should be done only when testing in the actual operating environment cannot be done. When MIC is a factor in the test, microbial communities from the actual environment of interest must be used. Pure cultures of single types of microbes cannot provide conditions present in the actual operating environment.

Plant or field corrosion tests are useful for

1. Selection of the most suitable material to withstand a particular environment and to estimate its probable durability in that environment
2. Study of the effectiveness of means of preventing corrosion

### CORROSION TESTING: LABORATORY TESTS

Metals and alloys do not respond alike to all the influences of the many factors that are involved in corrosion. Consequently, it is impractical to establish any universal standard laboratory procedures for corrosion testing except for inspection tests. However, some details of laboratory testing need careful attention in order to achieve useful results.

In the selection of materials for the construction of a chemical plant, resistance to the corroding medium is often the determining factor; otherwise, the choice will fall automatically on the cheapest material mechanically suitable. Laboratory corrosion tests are frequently the quickest and most satisfactory means of arriving at a preliminary selection of the most suitable materials to use. Unfortunately, however, it is not yet within the state of the art of laboratory tests to predict with accuracy the behavior of the selected material under plant-operating conditions. The outstanding difficulty lies not so much in carrying out the test as in interpreting the results and translating

\*Includes information from papers by Oliver W. Siebert, John C. Stoecker II, and Ann Van Orden, courtesy of NACE International; Oliver W. Siebert and John R. Scully, courtesy of ASTM; John R. Scully and Robert G. Kelly, courtesy of ASM; and Metal Samples Company, Division of Alabama Specialty Products Company, Munford, Alabama.

them into terms of plant performance. A laboratory test of the conventional type gives mainly one factor—the chemical resistance of the proposed material to the corrosive agent. There are numerous other factors entering into the behavior of the material in the plant, such as dissolved gases, velocity, turbulence, abrasion, crevice conditions, hot-wall effects, cold-wall effects, stress levels of metals, trace impurities in corrodent that act as corrosion inhibitors or accelerators, and variations in composition of corrodent.

**Immersion Test** One method of determining the chemical-resistance factor, the so-called **total-immersion test**, represents an unaccelerated method that has been found to give reasonably concordant results in approximate agreement with results obtained on the large scale when the other variables are taken into account. Various other tests have been proposed and are in use, such as salt-spray, accelerated electrolytic, alternate-immersion, and aerated-total-immersion; but in view of the numerous complications entering into the translation of laboratory results into plant results the simplest test is considered the most desirable for routine preliminary work, reserving special test methods for special cases. The total-immersion test serves quite well to eliminate materials that obviously cannot be used; further selection among those materials which apparently can be used can be made on the basis of a knowledge of the properties of the materials concerned and the working conditions or by constructing larger-scale equipment of the proposed materials in which the operating conditions can be simulated.

The National Association of Corrosion Engineers (NACE) TMO169-95 "Standard Laboratory Corrosion Testing of Metals for the Process Industries," and ASTM G31 "Recommended Practice for Laboratory Immersion Corrosion Testing of Metals" are the general guides for immersion testing. Small pieces of the candidate metal are exposed to the medium, and the loss of mass of the metal is measured for a given period of time. Immersion testing remains the best method to eliminate from further consideration those materials that obviously cannot be used. This technique is frequently the quickest and most satisfactory method of making a preliminary selection of the best candidate materials.

Probably the most serious disadvantage of this method of corrosion study is the assumed average-time weight loss. The corrosion rate could be high initially and then decrease with time (it could fall to zero). In other cases the rate of corrosion might increase very gradually with time or it could cycle or be some combination of these things.

The description that follows is based on these standards.

**Test Piece**° The size and the shape of specimens will vary with the purpose of the test, nature of the material, and apparatus used. A large surface-to-mass ratio and a small ratio of edge area to total area are desirable. These ratios can be achieved through the use of rectangular or circular specimens of minimum thickness. Circular specimens should be cut preferably from sheet and not bar stock to minimize the exposed end grain.

A circular specimen of about 32-mm (1.25-in) diameter is a convenient shape for laboratory corrosion tests. With a thickness of approximately 3 mm (1/8 in) and an 8- or 11-mm- (5/16- or 7/8-in-) diameter hole for mounting, these specimens will readily pass through a 45/50 ground-glass joint of a distillation kettle. The total surface area of a circular specimen is given by the equation:

$$A = \frac{\pi}{2} (D^2 - d^2) + \pi D t + \pi d t$$

where  $t$  = thickness,  $D$  = diameter of the specimen, and  $d$  = diameter of the mounting hole. If the hole is completely covered by the mounting support, the final term ( $\pi d t$ ) in the equation is omitted.

Rectangular coupons [50 by 25 by 1.6 or 3.2 mm (2 by 1 by 1/16 or 1/8 in)] may be preferred as corrosion specimens, particularly if interface or liquid-line effects are to be studied by the laboratory test.

Shapes of typical (commercially available) test coupons are shown in Fig. 25-3: circular in Fig. 25-3a, rectangular in Fig. 25-3b, welded rectangular in Fig. 25-3c, and horseshoe stressed in Fig. 25-3d. Many desired shapes of coupons are also available in various sizes and can be obtained in any size, shape, material of construction, and surface finish

**FIG. 25-3** Typical commercially available test coupons: (a) circular; (b) rectangular; (c) welded rectangular; (d) horseshoe stressed.

## 25-14 MATERIALS OF CONSTRUCTION

required to fit unique laboratory test equipment. There are also a series of somewhat generic racks and holders for mounting corrosion coupons so that they may be installed, exposed, and recovered for examination, after the plant exposures. Several typical pieces of hardware are shown in Fig. 25-4: a pipeline insertion rack in Fig. 25-4a, a spool rack for general equipment exposures in Fig. 25-4b, and a flat bar rack for attachment to accessories within equipment in Fig. 25-4c.

All specimens should be measured carefully to permit accurate calculation of the exposed areas. An area calculation accurate to plus or minus 1 percent is usually adequate.

More uniform results may be expected if a substantial layer of metal is removed from the specimens to eliminate variations in condition of the original metallic surface. This can be done by chemical treatment (pickling), electrolytic removal, or grinding with a coarse abrasive paper or cloth, such as No. 50, using care not to work-harden the surface. At least  $2.5 \times 10^{-3}$  mm (0.0001 in) or 1.5 to 2.3 mg/cm<sup>2</sup> (10 to

15 mg/in<sup>2</sup>) should be removed. If clad alloy specimens are to be used, special attention must be given to ensure that excessive metal is not removed. After final preparation of the specimen surface, the specimens should be stored in a desiccator until exposure if they are not used immediately.

Specimens should be finally degreased by scrubbing with bleach-free scouring powder, followed by thorough rinsing in water and in a suitable solvent (such as acetone, methanol, or a mixture of 50 percent methanol and 50 percent ether), and air-dried. For relatively soft metals such as aluminum, magnesium, and copper, scrubbing with abrasive powder is not always needed and can mar the surface of the specimen. The use of towels for drying may introduce an error through contamination of the specimens with grease or lint. The dried specimen should be weighed on an analytic balance.

**Apparatus** A versatile and convenient apparatus should be used, consisting of a kettle or flask of suitable size (usually 500 to 5,000 mL), a

**FIG. 25-4** Corrosion racks used to expose corrosion samples in operating production equipment: (a) inside pipes; (b) inside process vessels; (c) to be bolted onto baffles and brackets with process vessels.

reflux condenser with atmospheric seal, a sparger for controlling atmosphere or aeration, a thermowell and temperature-regulating device, a heating device (mantle, hot plate, or bath), and a specimen-support system. If agitation is required the apparatus can be modified to accept a suitable stirring mechanism such as a magnetic stirrer. A typical resin-flask setup for this type of test is shown in Fig. 25-5. Open-beaker tests should *not* be used because of evaporation and contamination.

In more complex tests, provisions might be needed for continuous flow or replenishment of the corrosive liquid while simultaneously maintaining a controlled atmosphere.

Heat flux apparatus for testing materials for heat-transfer applications is shown in Fig. 25-6. Here the sample is at a higher temperature than the bulk solution.

If the test is to be a guide for the selection of a material for a particular purpose, the limits of controlling factors in service must be determined. These factors include oxygen concentration, temperature, rate of flow, pH value, and other important characteristics.

The **composition of the test solution** should be controlled to the fullest extent possible and be described as thoroughly and as accurately as possible when the results are reported. Minor constituents should not be overlooked because they often affect corrosion rates. Chemical content should be reported as percentage by weight of the solution. Molarity and normality are also helpful in defining the concentration of chemicals in the test solution. The composition of the test solution should be checked by analysis at the end of the test to determine the extent of change in composition, such as might result from evaporation.

**Temperature of Solution** Temperature of the corroding solution should be controlled within  $\pm 1^\circ\text{C}$  ( $\pm 1.8^\circ\text{F}$ ) and must be stated in the report of test results.

For tests at ambient temperatures, the tests should be conducted at the highest temperature anticipated for stagnant storage in summer months. This temperature may be as high as 40 to 45°C (104 to 113°F) in some localities. The variation in temperature should be reported also (e.g., 40°C  $\pm$  2°C).

**Aeration of Solution** Unless specified, the solution should not be aerated. Most tests related to process equipment should be run with the natural atmosphere inherent in the process, such as the vapors of the boiling liquid. If aeration is used, the specimens should not be located in the direct air stream from the sparger. Extraneous effects can be encountered if the air stream impinges on the specimens.

**Solution Velocity** The effect of velocity is not usually determined in laboratory tests, although specific tests have been designed for this purpose. However, for the sake of reproducibility some velocity control is desirable.

Tests at the boiling point should be conducted with minimum possible heat input, and boiling chips should be used to avoid excessive turbulence and bubble impingement. In tests conducted below the boiling point, thermal convection generally is the only source of liquid velocity. In test solutions of high viscosities, supplemental controlled stirring with a magnetic stirrer is recommended.

**Volume of Solution** Volume of the test solution should be large enough to avoid any appreciable change in its corrosiveness through either exhaustion of corrosive constituents or accumulation of corrosion products that might affect further corrosion.

A suitable volume-to-area ratio is 20 mL (125 mL) of solution/cm<sup>2</sup> (in<sup>2</sup>) of specimen surface. This corresponds to the recommendation of ASTM Standard A262 for the Huey test. The preferred volume-to-area ratio is 40 mL/cm<sup>2</sup> (250 mL/in<sup>2</sup>) of specimen surface, as stipulated in ASTM Standard G31, Laboratory Immersion Testing of Materials.

**Method of Supporting Specimens** The supporting device and container should not be affected by or cause contamination of the test solution. The method of supporting specimens will vary with the apparatus used for conducting the test but should be designed to insulate the specimens from each other physically and electrically and to insulate the specimens from any metallic container or supporting device used with the apparatus.

Shape and form of the specimen support should assure free contact of the specimen with the corroding solution, the liquid line, or the vapor phase, as shown in Fig. 25-5. If clad alloys are exposed, special procedures are required to ensure that only the cladding is exposed (unless the purpose is to test the ability of the cladding to protect cut edges in the test solution). Some common supports are glass or

FIG. 25-5 Laboratory-equipment arrangement for corrosion testing. (Based on NACE Standard TMO169-95.)

FIG. 25-6 Laboratory setup for the corrosion testing of heat-transfer materials.

ceramic rods, glass saddles, glass hooks, fluorocarbon plastic strings, and various insulated or coated metallic supports.

**Duration of Test** Although the duration of any test will be determined by the nature and purpose of the test, an excellent procedure for evaluating the effect of time on corrosion of the metal and also on the corrosiveness of the environment in laboratory tests has been presented by Wachter and Treseder [*Chem. Eng. Prog.*, 315-326 (June 1947)]. This technique is called the **planned-interval test**. Other procedures that require the removal of solid corrosion products between exposure periods will not measure accurately the normal changes of corrosion with time.

Materials that experience severe corrosion generally do not need lengthy tests to obtain accurate corrosion rates. Although this assumption is valid in many cases, there are exceptions. For example, lead exposed to sulfuric acid corrodes at an extremely high rate at first while building a protective film; then the rate decreases considerably, so that further corrosion is negligible. The phenomenon of forming a protective film is observed with many corrosion-resistant materials, and therefore short tests on such materials would indicate high corrosion rates and would be completely misleading.

Short-time tests also can give misleading results on alloys that form passive films, such as stainless steels. With borderline conditions, a prolonged test may be needed to permit breakdown of the passive film and subsequently more rapid attack. Consequently, tests run for long periods are considerably more realistic than those conducted for short durations. This statement must be qualified by stating that corrosion should not proceed to the point at which the original specimen size or the exposed area is drastically reduced or the metal is perforated.

If anticipated corrosion rates are moderate or low, the following equation gives a suggested test duration:

$$\begin{aligned} \text{Duration of test, } h &= \frac{78,740}{\text{corrosion rate, mm/y}} \\ &= \frac{2000}{\text{corrosion rate, mils/y}} \end{aligned}$$

**Cleaning Specimens after Test** Before specimens are cleaned, their appearance should be observed and recorded. Locations of deposits, variations in types of deposits, and variations in corrosion products are extremely important in evaluating localized corrosion such as pitting and concentration-cell attack.

Cleaning specimens after the test is a vital step in the corrosion-test procedure and, if not done properly, can give rise to misleading test results. Generally, the cleaning procedure should remove all corrosion products from specimens with a minimum removal of sound metal. Set rules cannot be applied to cleaning because procedures will vary with the type of metal being cleaned and the degree of adherence of corrosion products.

**Mechanical cleaning** includes scrubbing, scraping, brushing, mechanical shocking, and ultrasonic procedures. Scrubbing with a bristle brush and a mild abrasive is the most widely used of these methods; the others are used principally as supplements to remove heavily encrusted corrosion products before scrubbing. Care should be used to avoid the removal of sound metal.

**Chemical cleaning** implies the removal of material from the surface of the specimen by dissolution in an appropriate chemical agent. Solvents such as acetone, carbon tetrachloride, and alcohol are used to remove oil, grease, or resin and are usually applied prior to other methods of cleaning. Various chemicals are chosen for application to specific materials; some of these treatments in general use are outlined in the NACE standard.

**Electrolytic cleaning** should be preceded by scrubbing to remove loosely adhering corrosion products. One method of electrolytic cleaning that has been found to be useful for many metals and alloys is as follows:

Solution: 5 percent (by weight)  $\text{H}_2\text{SO}_4$   
 Anode: carbon or lead  
 Cathode: test specimen  
 Cathode current density: 20 A/dm<sup>2</sup> (129 A/in<sup>2</sup>)  
 Inhibitor: 2 cm<sup>3</sup> organic inhibitor per liter  
 Temperature: 74°C (165°F)  
 Exposure period: 3 min

Precautions must be taken to ensure good electrical contact with the specimen, to avoid contamination of the solution with easily reducible metal ions, and to ensure that inhibitor decomposition has not occurred. Instead of using 2 mL of any proprietary inhibitor, 0.5 g/L of inhibitors such as diorthotolyl thiourea or quinoline ethiodide can be used.

Whatever treatment is used to clean specimens after a corrosion test, its effect in removing metal should be determined, and the weight loss should be corrected accordingly. A "blank" specimen should be weighed before and after exposure to the cleaning procedure to establish this weight loss.

**Evaluation of Results** After the specimens have been reweighed, they should be examined carefully. Localized attack such as pits, crevice corrosion, stress-accelerated corrosion, cracking, or intergranular corrosion should be measured for depth and area affected.

Depth of localized corrosion should be reported for the actual test period and not interpolated or extrapolated to an annual rate. The rate of initiation or propagation of pits is seldom uniform. The size, shape, and distribution of pits should be noted. A distinction should be made between those occurring underneath the supporting devices (concentration cells) and those on the surfaces that were freely exposed to the test solution. An excellent discussion of pitting corrosion has been published [*Corrosion*, 25t (January 1950)].

The specimen may be subjected to simple bending tests to determine whether any **embrittlement** has occurred.

If it is assumed that localized or internal corrosion is not present or is recorded separately in the report, the **corrosion rate** or penetration can be calculated alternatively as

$$\frac{\text{Weight loss} \times 534}{(\text{Area})(\text{time})(\text{metal density})} = \text{mils/y (mpy)}$$

$$\frac{\text{Weight loss} \times 13.56}{(\text{Area})(\text{time})(\text{metal density})} = \text{mm/y (mmpy)}$$

where weight loss is in mg, area is in in<sup>2</sup> of metal surface exposed, time is in hours exposed, and density is in g/cm<sup>3</sup>. Densities for alloys can be obtained from the producers or from various metal handbooks.

The following **checklist** is a recommended guide for reporting all **important information and data**:

- Corrosive media and concentration (changes during test)
- Volume of test solution
- Temperature (maximum, minimum, and average)
- Aeration (describe conditions or technique)
- Agitation (describe conditions or technique)
- Type of apparatus used for test
- Duration of each test (start, finish)
- Chemical composition or trade name of metals tested
- Form and metallurgical conditions of specimens
- Exact size, shape, and area of specimens
- Treatment used to prepare specimens for test
- Number of specimens of each material tested and whether specimens were tested separately or which specimens were tested in the same container

Method used to clean specimens after exposure and the extent of any error expected by this treatment

Actual weight losses for each specimen  
 Evaluation of attack if other than general, such as crevice corrosion under support rod, pit depth and distribution, and results of microscopic examination or bend tests

Corrosion rates for each specimen expressed as millimeters (mils) per year

**Effect of Variables on Corrosion Tests** It is advisable to apply a factor of safety to the results obtained, the factor varying with the degree of confidence in the applicability of the results. Ordinarily, a factor of from 3 to 10 might be considered normal.

Among the more important points that should be considered in attempting to base plant design on laboratory corrosion-rate data are the following.

**Galvanic corrosion** is a frequent source of trouble on a large scale. Not only is the use of different metals in the same piece of equipment dangerous, but the effect of cold working may be sufficient to establish potential differences of objectionable magnitude between different

parts of the same piece of metal. The mass of metal in chemical apparatus is ordinarily so great and the electrical resistance consequently so low that a very small voltage can cause a very high current. Welding also may leave a weld of a different physical or chemical composition from that of the body of the sheet and cause localized corrosion.

Local variations in temperature and crevices that permit the accumulation of corrosion products are capable of allowing the formation of **concentration cells**, with the result of accelerated local corrosion.

In the laboratory, the **temperature** of the test specimen is that of the liquid in which it is immersed, and the measured temperature is actually that at which the reaction is taking place. In the plant (heat being supplied through the metal to the liquid in many cases), the temperature of the film of (corrosive) liquid on the inside of the vessel may be a number of degrees higher than that registered by the thermometer. As the relation between temperature and corrosion is a logarithmic one, the rate of increase is very rapid. Like other chemical reactions, the speed ordinarily increases twofold to threefold for each 10°C temperature rise, the actual relation being that of the equation  $\log K = A + (B/T)$ , where  $K$  represents the rate of corrosion and  $T$  the absolute temperature. This relationship, although expressed mathematically, must be understood to be a qualitative rather than strictly a quantitative one.

**Cold walls**, as in coolers or condensers, usually have somewhat decreased corrosion rates for the reason just described. However, in some cases, the decrease in temperature may allow the formation of a more corrosive second phase, thereby increasing corrosion.

The effect of **impurities** in either structural material or corrosive material is so marked (while at the same time it may be either accelerating or decelerating) that for reliable results the actual materials which it is proposed to use should be tested and not types of these materials. In other words, it is much more desirable to test the actual plant solution and the actual metal or nonmetal than to rely upon a duplication of either. Since as little as 0.01 percent of certain organic compounds will reduce the rate of solution of steel in sulfuric acid 99.5 percent and 0.05 percent bismuth in lead will increase the rate of corrosion over 1000 percent under certain conditions, it can be seen how difficult it would be to attempt to duplicate here all the significant constituents.

**Electrical Resistance** The measurement of corrosion by electrical resistance is possible by considering the change in resistance of a thin metallic wire or strip sensing element (probe) as its cross section decreases from a loss of metal. Since small changes in resistance are encountered as corrosion progresses, changes in temperature can cause enough change in the wire resistance to complicate the results. Commercial equipment, such as the Corrosometer®, have a protected reference section of the specimen in the modified electrical Wheatstone bridge (Kelvin) circuit to compensate for these temperature changes. Since changes in the resistance ratio of the probe are not linear with loss of section thickness, compensation for this variable must be included in the circuit. In operation, the specimen probe is exposed to the environment and instrument readings are periodically recorded. The corrosion rate is the loss of metal averaged between any two readings.

The corrosion rate can be studied by this method over very short periods of time, but not instantaneously. The environment does not have to be an electrolyte. Studies can be made in corrosive gas exposures. The main disadvantage of the technique is that local corrosion (pitting, crevice corrosion, galvanic, stress corrosion cracking, fatigue, and so forth) will probably not be progressively identified. If the corrosion product has an electrical conductivity approaching that of the lost metal, little or no corrosion will be indicated. The same problem will result from the formation of conducting deposits on the specimen.

The electrical-resistance measurement has nothing to do with the electrochemistry of the corrosion reaction. It merely measures a bulk property that is dependent upon the specimen's cross-section area. Commercial instruments are available (Fig. 25-7).

**Advantages** of the electrical-resistance technique are:

1. A corrosion measurement can be made without having to see or remove the test sample.
2. Corrosion measurements can be made quickly—in a few hours or days, or continuously. This enables sudden increases in corrosion rate to be detected. In some cases, it will be possible then to modify the process to decrease the corrosion.

FIG. 25-7 Typical retractable corrosion probe.

3. The method can be used to monitor a process to indicate whether the corrosion rate is dependent on some critical process variable.

4. Corrodent need not be an electrolyte (in fact, need not be a liquid).

5. The method can detect low corrosion rates that would take a long time to detect with weight-loss methods.

**Limitations** of the technique are:

1. It is usually limited to the measurement of uniform corrosion only and is not generally satisfactory for localized corrosion.

2. The probe design includes provisions to compensate for temperature variations. This feature is not totally successful. The most reliable results are obtained in constant-temperature systems.

**EMF versus pH (Pourbaix) Diagrams** Potential (EMF) versus pH equilibrium (Pourbaix) diagrams derived from physical property data about the metal and its environment provide a basis for the expression of a great amount of thermodynamic data about the corrosion reaction. These relatively simple diagrams graphically represent the thermodynamics of corrosion in terms of electromotive force, that is, an indication of oxidizing power and pH, or acidity. As an aid in corrosion prediction, their usefulness lies in providing direction for establishing a corrosion study program.

Figure 25-8 is a typical Pourbaix diagram. Generally, the diagrams show regions of immunity (the metal), passivity (the surface film), and corrosion (metallic ions). While of considerable qualitative usefulness, these diagrams have important limitations. Since they are calculated from thermodynamic properties, they represent equilibrium conditions and do not provide kinetic information. Thus, while they show conditions where corrosion will not occur, they do not necessarily indicate under what conditions corrosion will occur. To determine the quantitative value of corrosion, kinetic rate measurement would still be required. Pourbaix diagrams were developed for the study of pure metals. Since few engineering structures are made of pure metals, it is important to extend this technique to include information on the passive behavior of alloys of engineering interest. Values of the open circuit corrosion potential (OCP) or a controlled potential occur, if a steady site potential can be used in conjunction with the solution pH and these diagrams to show what component is stable in the system defined by a given pH and potential. Theoretical diagrams so developed estimate the corrosion product in various regions. The use of computers to construct diagrams for alloy systems provides an opportunity to mathematically overcome many of the limitations inherent in the pure metal system.

A potentiokinetic electrochemical hysteresis method of diagram construction has led to consideration of three-dimensional Pourbaix diagrams for alloy systems useful in alloy development, evaluation of the influence of crevices, prediction of the tendency for dealloying, and the inclusion of kinetic data on the diagram is useful in predicting corrosion rather than just the absence of damage. These diagrams are kinetic, not thermodynamic, expressions. The two should not be confused as being the same reaction, as they are not.

**Tafel Extrapolation** Corrosion is an electrochemical reaction of a metal and its environment. When corrosion occurs, the current that flows between individual small anodes and cathodes on the metal surface causes the electrode potential for the system to change. While

FIG. 25-8 EMF-pH diagram for an iron-water system at 25°C. All ions are at an activity of  $10^{-6}$ .

this current cannot be measured, it can be evaluated indirectly on a metal specimen with an inert electrode and an external electrical circuit. Polarization is described as the extent of the change in potential of an electrode from its equilibrium potential caused by a net current flow to or from the electrode, galvanic or impressed (Fig. 25-9).

Electrochemical techniques have been used for years to study fundamental phenomenological corrosion reactions of metals in corrosive environments. Unfortunately, the learning curve in the reduction of these electrochemical theories to practice has been painfully slow. However, a recent survey has shown that many organizations in the chemical process industries are now adding electrochemical methods to their materials selection techniques. Laboratory electrochemical tests of metal/environment systems are being used to show the degree of compatibility and describe the limitations of those relationships. The general methods being used include electrical resistance, Tafel extrapolation, linear polarization, and both slow and rapid-scan potentiodynamic polarization. Depending upon the study technique used, it has also been possible to indicate the tendency of a given system to suffer local pitting or crevice attack or both. These same tools have been the basis of design protection of less-noble structural metals.

To study the anode reaction of a specimen in an environment, sufficient current is applied to change the freely corroding potential of the metal in a more electropositive direction with respect to the inert electrode (acting as a cathode). The opposite of this so-called anodic polarization is cathodic polarization. Polarization can be studied equally well by varying the potential and measuring the resultant changes in the current. Both of the theoretical (true) polarization curves are straight lines when plotted on a semilog axis. The corrosion current can be measured from the intersection of the corrosion potential and

FIG. 25-9 Tafel extrapolation and linear polarization curves.

either the anodic or cathodic curve. The corrosion rate of the system is a function of that corrosion current. Experimentally derived curves are not fully linear because of the interference from the reactions between the anodes and cathodes in the region close to the corrosion potential. IR losses often obscure the Tafel behavior. Away from the corrosion potential, the measured curves match the theoretical (true) curves. The matching region of the measured curves is called the **Tafel region**, and their (Tafel) slopes are constant. Corrosion rates can be calculated from the intersection of the corrosion potential and the extrapolation of the Tafel region. The main advantage of the technique is that it is quick; curves can be generated in about an hour.

The technique is of limited value where more than one cathodic reduction reaction occurs. In most cases it is difficult to identify a sufficient linear segment of the Tafel region to extrapolate accurately. Since currents in the Tafel region are one to two orders of magnitude larger on the log scale than the corrosion current, relatively large currents are required to change the potentials from what they are at the corrosion potential. The environment must be a conductive solution. The Tafel technique does not indicate local attack, only an average, uniform corrosion rate.

The primary use of this laboratory technique today is as a quick check to determine the order of magnitude of a corrosion reaction. Sometimes the calculated rate from an immersion test does not "look" correct when compared to the visual appearance of the metal coupon. While the specific corrosion rate number determined by Tafel extrapolation is seldom accurate, the method remains a good confirmation tool.

**Linear Polarization** Some of the limitations of the Tafel extrapolation method can be overcome by using the linear-polarization technique to determine the corrosion rate. A relationship exists between the slope of the polarization curves  $E/I$  (with units of resistance, linear polarization is sometimes termed *polarization resistance*) and instantaneous corrosion rates of a freely corroding alloy. The polarization resistance is determined by measuring the amount of applied current needed to change the corrosion potential of the freely corroding specimen by about 10-mV deviations. The slope of the curves thus generated is directly related to the corrosion rate by Faraday's law. Several instruments are available that are used in linear polarization work. The main advantage is that each reading on the instrument can be translated directly into a corrosion rate.

As with all electrochemical studies, the environment must be electrically conductive. The corrosion rate is directly dependent on the Tafel slope. The Tafel slope varies quite widely with the particular corroding system and generally with the metal under test. As with the

Tafel extrapolation technique, the Tafel slope generally used is an assumed, more or less average value. Again, as with the Tafel technique, the method is not sensitive to local corrosion.

The amount of externally applied current needed to change the corrosion potential of a freely corroding specimen by a few millivolts (usually 10 mV) is measured. This current is related to the corrosion current, and therefore the corrosion rate, of the sample. If the metal is corroding rapidly, a large external current is needed to change its potential, and vice versa.

The measuring system consists of four basic elements:

1. **Electrodes.** Test and reference electrodes and, in some cases, an auxiliary electrode.
2. **Probe.** It connects the electrodes in the corrodent on the inside of a vessel to the electrical leads.
3. **Electrical leads.** They run from the probe to the current source and instrument panel.
4. **Control system.** Current source (batteries), ammeter, voltmeter, instrument panel, and so on.

Commercial instruments have either two or three electrodes. Also, there are different types of three-electrode systems. The application and limitations of the instruments are largely dependent upon these electrode systems.

**Potentiodynamic Polarization** Not all metals and alloys react in a consistent manner in contact with corrosive fluids. One of the common intermediate reactions of a metal (surface) is with oxygen, and those reactions are variable and complex. Oxygen can sometimes function as an electron acceptor; that is, oxygen can act as an oxidizing agent, and remove the "protective" film of hydrogen from the cathodic area, **cathodic depolarization**. The activation energy of the oxygen/hydrogen reaction is very large. This reaction does not normally occur at room temperature at any measurable rate. In other cases, oxygen can form protective oxide films. The long-term stability of these oxides also varies; some are soluble in the environment, others form more stable and inert or passive films.

Because corrosion is an electrochemical process, it is possible to evaluate the overall reaction by the use of an external electrical circuit called a **potentiostat**. When corrosion occurs, a potential difference exists between the metal and its ions in solution. It is possible to electrically control this potential; changes in potential cause changes in current (corrosion). Oxidation is a reaction with a loss of electrons (anodic—the reacting electrode is the anode); reduction is a reaction with a gain of electrons (cathodic—the reacting electrode is the cathode). Rather than allowing the electrons being evolved from the corrosion reaction to combine with hydrogen, these electrons can be removed by internal circuitry, and sent through a potentiostat, causing a cathodic (or anodic) reaction to occur at a platinum counter electrode. This is always true for the external polarization method; it is not unique for a potentiostat.

It is now well established that the activity of pitting, crevice corrosion, and stress-corrosion cracking is strongly dependent upon the corrosion potential (i.e., the potential difference between the corroding metal and a suitable reference electrode). By using readily available electronic equipment, the quantity and direction of direct current required to control the corrosion potential in a given solution at a given selected value can be measured. A plot of such values over a range of potentials is called a polarization diagram. By using proper experimental techniques, it is possible to define approximate ranges of corrosion potential in which pitting, crevice corrosion, and stress-corrosion cracking will or will not occur. With properly designed probes, these techniques can be used in the field as well as in the laboratory.

The potentiostat has a three-electrode system: a reference electrode, generally a saturated calomel electrode (SCE); a platinum counter, or auxiliary, electrode through which current flows to complete the circuit; and a working electrode that is a sample of interest (Fig. 25-10). The potentiostat is an instrument that allows control of the potential, either holding constant at a given potential, stepping from potential to potential, or changing the potential anodically or cathodically at some linear rate.

In the study of the anode/cathode polarization behavior of a metal/environment system, the potentiostat provides a plot of the relationship of current changes resulting from changes in potential most often presented as a plot of log current density versus potential, or Evans

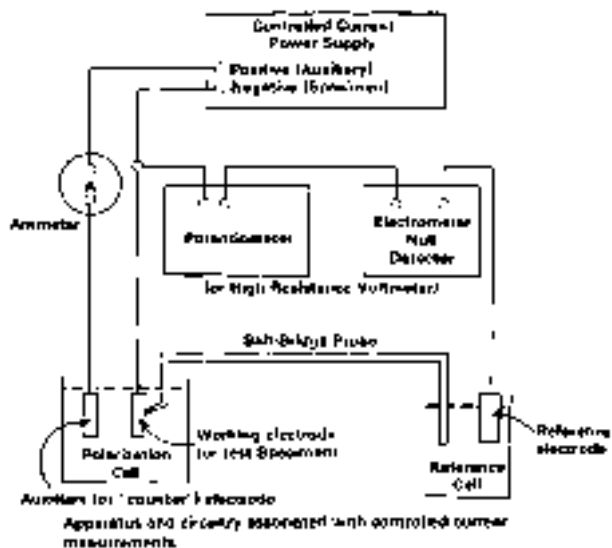

FIG. 25-10 The potentiostat apparatus and circuitry associated with controlled potential measurements of polarization curves.

diagram. A typical active/passive metal anodic polarization curve is seen in Fig. 25-11, generally showing the regions of active corrosion and passivity and a transpassive region.

**Scan Rates** Sweeping a range of potentials in the anodic (more electropositive) direction of a potentiodynamic polarization curve at a high scan rate of about 60 V/h (high from the perspective of the corrosion engineer, slow from the perspective of a physical chemist) is to indicate regions where intense anodic activity is likely. Second, for otherwise identical conditions, sweeping at a relatively slow rate of

FIG. 25-11 Typical electrochemical polarization curve for an active/passive alloy (with cathodic trace) showing active, passive, and transpassive regions and other important features. (NOTE:  $E_{pp}$  = primary passive potential,  $E_{corr}$  = freely corroding potential.)

potential change of about 1 V/h will indicate regions wherein relative inactivity is likely. The rapid sweep of the potential range has the object of minimizing film formation, so that the currents observed relate to relatively film-free or thin-film conditions. The object of the slow sweep rate experiment is to allow time for filming to occur. A zero scan rate provides the opportunity for maximum stability of the metal surface, but at high electropositive potentials the environment could be affected or changed. A rapid scan rate compromises the steady-state nature of the metal surface but better maintains the stability of the environment. Whenever possible, corrosion tests should be conducted using as many of the techniques available, potentiodynamic polarization at various scan rates, crevice, stress, velocity, and so forth. An evaluation of these several results, on a holistic basis, can greatly reduce or temper their individual limitations.

**Slow-Scan Technique** In ASTM G5 "Polarization Practice for Standard Reference Method for Making Potentiostatic and Potentiodynamic Anodic Polarization Measurements," all oxygen in the test solution is purged with hydrogen for a minimum of 0.5 h before introducing the specimen. The test material is then allowed to reach a steady state of equilibrium (open circuit corrosion potential,  $E_{corr}$ ) with the test medium before the potential scan is conducted. Starting the evaluation of a basically passive alloy that is already in its "stable" condition precludes any detailed study of how the metal reaches that protected state (the normal intersection of the theoretical anodic and cathodic curves is recorded as a zero applied current on the ASTM potentiostatic potential versus applied current diagram). These intersections between the anodic and cathodic polarization curves are the condition where the total oxidation rate equals the total reduction rate (ASTM G3 "Recommended Practice for Conventions Applicable to Electrochemical Measurements in Corrosion Testing").

Three general reaction types compare the activation-control reduction processes. In Fig. 25-12, in Case 1, the single reversible corrosion potential (anode/cathode intersection) is in the active region. A wide range of corrosion rates is possible. In Case 2, the cathodic curve intersects the anodic curve at three potentials, one active and two passive. If the middle active/passive intersection is not stable, the lower and upper

intersections indicate the possibility of very high corrosion rates. In Case 3, corrosion is in the stable, passive region, and the alloys generally passivate spontaneously and exhibit low corrosion rates. Most investigators report that the ASTM method is effective for studying Case 1 systems. An alloy-medium system exhibiting Case 2 and 3 conditions generally cannot be evaluated by this conventional ASTM method.

The potentiodynamic polarization electrochemical technique can be used to study and interpret corrosion phenomena. It may also furnish useful information on film breakdown or repair.

**Rapid-Scan Corrosion Behavior Diagram (CBD)** Basically, all the same equipment used in the conductance of an ASTM G5 slow-scan polarization study is used for rapid-scan CBDs (that is, a standard test cell, potentiostat, voltmeters, log converters, X-Y recorders, and electronic potential scanning devices). The differences are in technique: the slow scan is run at a potential sweep rate of about 0.6 V/h; the rapid-scan CBDs at about 50 V/h.

Different from the slow-scan technique, which is generally limited to Case 1 alloy/medium systems, the rapid-scan technique allows full anodic polarization study of alloys showing all Case 1, 2, and 3 behavior (Fig. 25-12). In Case 1, the single reversible corrosion potential (the anode/cathode intersection) is in the active region. A wide range of corrosion rates is possible. In Case 2, the cathodic curve intersects the anodic curve at three potentials, one in the active region and two in the passive. Since the middle active/passive intersection is not stable, the intersections indicate the possibility of very high corrosion rates depending on the environment or even slight changes to the exposure/environment system. In Case 3, the curves intersect in the most stable, passive region; the alloys generally passivate spontaneously and exhibit low corrosion rates. Case 2 exhibits the most corrosion, is difficult to study, and presents the most risk for materials of construction selection. Anything that can change the oxygen solubility of the oxidizing agent can alter the corrosion reaction.

The CBD diagram can provide various kinds of information about the performance of an alloy/medium system. The technique can be used for a direct calculation of the corrosion rate as well as for indicating the conditions of passivity and tendency of the metal to suffer local pitting and crevice attack. There are *benefits* from using the rapid-scan technique (the so-called corrosion behavior diagram, Fig. 25-13), and some *limitations* (when compared to the aforementioned slow-scan technique). Since *none* of the electrochemical corrosion test techniques that are currently in vogue, be they the slow-scan, rapid-scan, cyclic potentiodynamic polarization, EIS/AC impedance, or frequency modulation, are, in and of themselves, a true evaluation, measurement, and portrayal of the corrosion reaction being studied; only during the so-called open-circuit potential are we viewing real-life corrosion. Then why are these several electrochemical test methods used? Because (of those various test methods) each provides some valuable information that is more accurate (or not available) than that obtained when using some different test method. The more experienced the electrochemist in understanding these differences, the more closely she or he is able to approach accuracy in her or his corrosion understanding and thus results. For example, in designing an anodic protection system, one of the most critically sensitive parameters is the optimum protection potential at which the corrosion rate of the metal is able to be maintained at its lowest value (the true, lowest anodic protection control is not necessarily the whole length of the passive area of the  $E$  versus  $\log I$  curve; see Fig. 25-11). Thus (conservatively), the control set point should be selected at the midpoint of the lowest corrosion rate (LCR) of the CBD, i.e., the region of protective oxide formation. If for no other reason than that, the CBD may be a test technique of choice for that anodic protection study. When using electrochemical test methods, many electrochemists try to employ a variety of test methods to arrive at the optimum selection of choice for any MOC study.

Those desiring a more detailed review of the subject of electrochemistry (and/or corrosion testing using electrochemistry) are directed to additional reference material from the following: Perry's *Chemical Engineers' Handbook*, 7th ed., Sec. 28, O. W. Siebert and J. G. Stoecker, "Materials of Construction," pp. 28-11 to 28-20, 1997; J. G. Stoecker, O. W. Siebert, and P. E. Morris, "Practical Applications

FIG. 25-12 Six possible types of behavior for an active/passive alloy in a corrosive environment.

FIG. 25-13 Corrosion behavior diagram (CBD).

of Potentiodynamic Polarization Curves in Materials Selection," *Materials Performance*, vol. 22, no. 11, pp. 13-22, November 1983; O. W. Siebert, "Correlation of Laboratory Electrochemical Investigations with Field Application of Anodic Protection," *Materials Performance*, vol. 20, no. 2, pp. 38-43, February 1981; and the assorted historical literature of Stern, Geary, Evans, Sudbury, Riggs, Pourbaix, and Edeleanu, and other studies referred to in their publications.

**Crevice Corrosion Prediction** The most common type of localized corrosion is the occluded mode crevice corrosion. Pitting can, in effect, be considered a self-formed crevice. A crevice must be wide enough to permit liquid entry, but sufficiently narrow to maintain a stagnant zone. It is nearly impossible to build equipment without mechanical crevices; on a microlevel, scratches can be sufficient crevices to initiate or propagate corrosion in some metal/environment systems. The conditions in a crevice can, with time, become a different and much more aggressive environment than those on a nearby, clean, open surface. Crevices may also be created by factors foreign to the original system design, such as deposits, corrosion products, and so forth. In many studies, it is important to know or to be able to evaluate the crevice corrosion sensitivity of a metal to a specific environment and to be able to monitor a system for predictive maintenance.

Historically, the immersion test technique involved the use of a crevice created by two metal test specimens clamped together or a metal specimen in contact with an inert plastic or ceramic. The Materials Technology Institute of the Chemical Process Industries, Inc. (MTI) funded a study that resulted in an electrochemical cell to monitor crevice corrosion. It consists of a prepared crevice containing an anode that is connected through a zero-resistance ammeter to a freely exposed cathode. A string bridge provides a solution path that is attached externally to the cell. The electrochemical cell is shown in Fig. 25-14. A continuous, semiquantitative, real-time indication of crevice corrosion is provided by the magnitude of the current flowing between an anode and a cathode, and a qualitative signal is provided by shifts in electrode potential. Both the cell current and electrode potential produced by the test correlate well with the initiation and

FIG. 25-14 Schematic diagram of the electrochemical cell used for crevice corrosion testing. Not shown are three hold-down screws, gas inlet tube, and external thermocouple tube.

propagation of crevice corrosion. During development of the MTI test technique, results were compared with crevice corrosion produced by a grooved TFE Teflon® plastic disk sandwich-type crevice cell. In nearly every instance, corrosion damage on the anode was similar in severity to that produced by the sandwich-type cell.

**Velocity** For corrosion to occur, an environment must be brought into contact with the metal surface and the metal atoms or ions must be allowed to be transported away. Therefore, the rate of transport of the environment with respect to a metal surface is a major factor in the corrosion system. Changes in velocity may increase or decrease attack depending on its effect involved. A varying quantity of dissolved gas may be brought in contact with the metal, or velocity changes may alter diffusion or transfer of ions by changing the thickness of the boundary layer at the surface. The boundary layer, which is not stagnant, moves except where it touches the surface. Many metals depend upon the development of a protective surface for their corrosion resistance. This may consist of an oxide film, a corrosion product, an adsorbed film of gas, or other surface phenomena. The removal of these surfaces by effect of the fluid velocity exposes fresh metal, and as a result, the corrosion reaction may proceed at an increasing rate. In these systems, corrosion might be minimal until a so-called **critical velocity** is attained where the protective surface is damaged or removed and the velocity is too high for a stable film to reform. Above this critical velocity, the corrosion may increase rapidly.

The NACE Landrum Wheel velocity test, originally TM0270-72, is typical of several mechanical-action immersion test methods to evaluate the effects of corrosion. Unfortunately, these laboratory simulation techniques did not consider the fluid mechanics of the environment or metal interface, and service experience very seldom supports the test predictions. A rotating cylinder within a cylinder electrode test system has been developed that operates under a defined hydrodynamics relationship (Figs. 25-15 and 25-16). The assumption is that if the rotating electrode operates at a shear stress comparable to that in plant geometry, the mechanism in the plant geometry may be modeled in the laboratory. Once the mechanism is defined, the appropriate relationship between fluid flow rate and corrosion rate in the plant equipment as defined by the mechanism can be used to predict the expected corrosion

\*See Review Paper by David C. Silverman, courtesy of NACE International.

FIG. 25-15 Rotating cylinder electrode apparatus.

rate. If fluid velocity does affect the corrosion rate, the degree of mass transfer control, if that is the controlling mechanism (as opposed to activation control), can be estimated. Conventional potentiodynamic polarization scans are conducted as described previously. In other cases, the corrosion potential can be monitored at a constant velocity until steady state is attained. While the value of the final corrosion potential is virtually independent of velocity, the time to reach steady state may be dependent on velocity. The mass-transfer control of the corrosion potential can be proportional to the velocity raised to its appropriate exponent. The rate of breakdown of a passive film is velocity-sensitive. To review a very detailed and much needed refinement of the information and application of the rotating electrode technique as used for evaluation of the effect of velocity on corrosion, the reader is directed to a recent seminal study by David C. Silverman, "The Rotating Cylinder Electrode for Examining Velocity-Sensitive Corrosion—A Review," *Corrosion*, vol. 60, no. 11, pp. 1003–1023, Nov. 2004.

**Environmental Cracking** The problem of environmental cracking of metals and their alloys is very important. Of all the failure mechanism tests, the test for stress corrosion cracking (SCC) is the most illusive. Stress corrosion is the acceleration of the rate of corrosion damage by static stress. SCC, the limiting case, is the spontaneous cracking that may result from combined effects of stress and corrosion. It is important to differentiate clearly between **stress corrosion cracking** and **stress accelerated corrosion**. Stress corro-

FIG. 25-16 Inner rotating cylinder used in laboratory apparatus of Fig. 25-15.

sion cracking is considered to be limited to cases in which no significant corrosion damage occurs in the absence of a corrosive environment. The material exhibits normal mechanical behavior under the influence of stress; before the development of a stress corrosion crack, there is little deterioration of strength and ductility. Stress corrosion cracking is the case of an interaction between chemical reaction and mechanical forces that results in structural failure that otherwise would not occur. SCC is a type of brittle fracture of a normally ductile material by the interaction between specific environments and mechanical forces, for example, tensile stress. Stress corrosion cracking is an incompletely understood corrosion phenomenon. Much research activity (aimed mostly at mechanisms) plus practical experience has allowed crude empirical guidelines, but these contain a large element of uncertainty. No single chemical, structural, or electrochemical test method has been found to respond with enough consistent reproducibility to known crack-causing environmental/stressed metal systems to justify a high confidence level.

As was cited in the case of immersion testing, most SCC test work is accomplished using mechanical, nonelectrochemical methods. It has been estimated that 90 percent of all SCC testing is handled by one of the following methods: (1) constant strain, (2) constant load, or (3) precracked specimens. Prestressed samples, such as are shown in Fig. 25-17, have been used for laboratory and field SCC testing. The variable observed is "time to failure or visible cracking." Unfortunately, such tests do not provide acceleration of failure.

Since SCC frequently shows a fairly long induction period (months to years), such tests must be conducted for very long periods before reliable conclusions can be drawn.

In the constant-strain method, the specimen is stretched or bent to a fixed position at the start of the test. The most common shape of

FIG. 25-17 Specimens for stress-corrosion tests. (a) Bent beam. (b) C ring. (c) U bend. (d) Tensile. (e) Tensile. (f) Tensile. (g) Notched C ring. (h) Notched tensile. (i) Precracked, wedge open-loading type. (j) Precracked, cantilever beam. [Chem. Eng., 78, 159 (Sept. 20, 1971).]

the specimens used for constant-strain testing is the U-bend, hair-pin, or horseshoe type. A bolt is placed through holes in the legs of the specimen, and it is loaded by tightening a nut on the bolt. In some cases, the stress may be reduced during the test as a result of creep. In the constant-load test the specimen is supported horizontally at each end and is loaded vertically downward at one or two points and has maximum stress over a substantial length or area of the specimen. The load applied is a predetermined, fixed dead weight. Specimens used in either of these tests may be precracked to assign a stress level or a desired location for fracture to occur or both as is used in fracture mechanics studies. These tensile-stressed specimens are then exposed in situ to the environment of study.

**Slow Strain-Rate Test** In its present state of development, the results from slow strain-rate tests (SSRT) with electrochemical monitoring are not always completely definitive; but, for a short-term test, they do provide considerable useful SCC information. Work in our laboratory shows that the SSRT with electrochemical monitoring and the U-bend tests are essentially equivalent in sensitivity in finding SCC. The SSRT is more versatile and faster, providing both mechanical and electrochemical feedback during testing.

The SSRT is a test technique where a tension specimen is slowly loaded in a test frame to failure under prescribed test conditions. The normal test extension rates are from  $2.54 \times 10^{-7}$  to  $2.54 \times 10^{-10}$  m/s ( $10^{-5}$  to  $10^{-8}$  in/s). Failure times are usually 1 to 10 days. The failure mode will be either SCC or tensile overload, sometimes accelerated by corrosion. An advantage behind the SSRT, compared to constant-strain tests, is that the protective surface film is thought to be ruptured mechanically during the test, thus giving SCC an opportunity to progress. To aid in the selection of the value of the potential at which the metal is most sensitive to SCC that can be applied to accelerate SSRT, potentiodynamic polarization scans are conducted as described previously. It is common for the potential to be monitored during the conduct of the SSRT. The strain rates that generate SCC in various metals are reported in the literature. There are several disadvantages to the SSRT. First, indications of failure are not generally observed until the tension specimen is plastically stressed, sometimes significantly, above the yield strength of the metal. Such high-stressed conditions can be an order of magnitude higher than the intended operating stress conditions. Second, crack initiation must occur fairly rapidly to have sufficient crack growth that can be detected using the SSRT. The occurrence of SCC in metals requiring long initiation times may go undetected.

**Modulus Measurements** Another SCC test technique is the use of changes of modulus as a measure of the damping capacity of a metal. It is known that a sample of a given test material containing cracks will have a lower effective modulus than does a sample of identical material free of cracks. The technique provides a rapid and reliable evaluation of the susceptibility of a sample material to SCC in a specific environment. The so-called internal friction test concept can also be used to detect and probe nucleation and progress of cracking and the mechanisms controlling it.

The Young's modulus of the specimen is determined by accurately measuring its resonant frequency while driving it in a standing longitudinal wave configuration. A Marx composite piezoelectric oscillator is used to drive the specimen at a resonant frequency. The specimen is designed to permit measurements while undergoing applied stress and while exposed to an environmental test solution. The specimens are three half-wavelengths long; the gripping nodes and solution cup are silver-soldered on at displacement nodes, so they do not interfere with the standing wave. As discussed for SSRT, potentiodynamic polarization scans are conducted to determine the potential that can be applied to accelerate the test procedure. Again, the potential can be monitored during a retest, as is the acoustic emission (AE) as an indicator of nucleation and progress of cracking.

**Conjunctive Use of Slow- and Rapid-Scan Polarization** The use of the methods discussed in the preceding requires a knowledge of the likely potential range for SCC to occur. Potentiodynamic polarization curves can be used to predict those SCC-sensitive potential ranges. The technique involves conducting both slow- and rapid-scan sweeps in the anodic direction of a range of potentials. Comparison of the two curves will indicate any ranges of potential within which high anodic activity in the film-free condition reduces to insignificant activ-

ity when the time requirements for film formation are met. This should indicate the range of potentials within which SCC is likely. Most of the SCC theories presently in vogue predict these domains of behavior to be between the primary passive potential and the onset of passivity. This technique shortens the search for that SCC potential.

**Separated Anode/Cathode** Realizing, as noted in the preceding, that localized corrosion is usually active to the surrounding metal surface, a stress specimen with a limited area exposed to the test solution (the anode) is electrically connected to an unstressed specimen (the cathode). A potentiostat, used as a zero-resistance ammeter, is placed between the specimens for monitoring the galvanic current. It is possible to approximately correlate the galvanic current  $I_g$  and potential to crack initiation and propagation, and, eventually, catastrophic failure. By this arrangement, the galvanic current  $I_g$  is independent of the cathode area. In other words, the potential of the anode follows the corrosion potential of the cathode during the test. The SSRT apparatus discussed previously may be used for tensile loading.

**Fracture Mechanics Methods** These have proved very useful for defining the minimum stress intensity  $K_{ISCC}$  at which stress corrosion cracking of high-strength, low-ductility alloys occurs. They have so far been less successful when applied to high-ductility alloys, which are extensively used in the chemical-process industries.

Work on these and other new techniques continues, and it is hoped that a truly reliable, accelerated test or tests will be defined.

**Electrochemical Impedance Spectroscopy (EIS) and AC Impedance\*** Many direct-current test techniques assess the overall corrosion process occurring at a metal surface, but treat the metal/solution interface as if it were a pure resistor. Problems of accuracy and reproducibility frequently encountered in the application of direct-current methods have led to increasing use of electrochemical impedance spectroscopy (EIS).

Electrode surfaces in electrolytes generally possess a surface charge that is balanced by an ion accumulation in the adjacent solution, thus making the system electrically neutral. The first component is a double layer created by a charge difference between the electrode surface and the adjacent molecular layer in the fluid. Electrode surfaces may behave at any given frequency as a network of resistive and capacitive elements from which an electrical impedance may be measured and analyzed.

The application of an impressed alternating current on a metal specimen can generate information on the state of the surface of the specimen. The corrosion behavior of the surface of an electrode is related to the way in which that surface responds to this electrochemical circuit. The AC impedance technique involves the application of a small sinusoidal voltage across this circuit. The frequency of that alternating signal is varied. The voltage and current response of the system are measured.

The so-called white-noise analysis by the fast Fourier transform technique (FFT) is another viable method. The entire spectrum can be derived from one signal. The impedance components thus generated are plotted on either a Nyquist (real versus imaginary) or Bode (log real versus log frequency plus log phase angle versus log frequency) plot. These data are analyzed by computer; they can be used to determine the polarization resistance and, thus, the corrosion rate if Tafel slopes are known. It is also thought that the technique can be used to monitor corrosion by examining the real resistance at high and low frequency and by assuming the difference is the polarization resistance. This can be done in low- and high-conductivity environments. Systems prone to suffer localized corrosion have been proposed to be analyzed by AC impedance and should aid in determining the optimum scan rate for potentiodynamic scans.

The use of impedance electrochemical techniques to study corrosion mechanisms and to determine corrosion rates is an emerging technology. Electrode impedance measurements have not been widely used, largely because of the sophisticated electrical equipment required to make these measurements. Recent advantages in microelectronics and computers has moved this technique almost overnight from being an academic experimental investigation of the concept

\*Excerpted from papers by Oliver W. Siebert, courtesy of NACE International and ASTM.

itself to one of shelf-item commercial hardware and computer software, available to industrial corrosion laboratories.

**Other Electrochemical Test Techniques** A seminal summary of the present state of electrochemical test techniques can be found in John R. Scully, Chapter 7, "Electrochemical Tests," 2005 *ASTM Manual* 20. Professor Scully performs a praiseworthy job of presenting the theories associated with the mechanisms of corrosion, addressing both the thermodynamics and the kinetics of their electrode reactions. He then follows with a detailed encapsulation of major test methods being used in the academic and industrial research laboratories throughout the world for both basic information as well as to predict the scope and types of metallic corrosion experienced. In addition to some of those methods (already) addressed in *Perry's* above, we have noted several others from his presentation, wherein he has provided a much more thorough review, e.g., concentration polarization effects, frequency modulation methods, electronic noise resistance, methods based upon mixed-potential theory, scratch-repassivation method for local corrosion, and many more. The editors of this section of *Perry's* recommend this timely ASTM review for readers who need a greater treatment of electrochemical corrosion testing than is included in this presentation. In addition, Prof. Scully and his associate at the University of Virginia, Prof. Robert G. Kelly, have coauthored a similar quality presentation, "Methods for Determining Aqueous Corrosion Reaction Rates," in the 2005 *ASM Metals Handbook*, vol. 13.

**Use and Limitations of Electrochemical Techniques** A major caution must be noted as to the general, indiscriminate use of many electrochemical tests. Corrosion is a surface phenomenon. It must be kept in mind that the only condition present during any type of corrosion test that is a true representation of the real-life circumstance is the so-called open-circuit potential (OCP). The OCP is the electrical circuit that exists on the metal surface during the naturally spontaneous accumulation of the electrical potential that forms on the metal surface when exposed to a liquid environment. Any kind of an electrical current that is *added* to that surface is an artifact that no longer represents the true nature of that corrosion reaction. Is this to say that any form of induced electrical variable makes any corrosion test invalid? Absolutely not. Collectively, we have devised a number of unique electronic instruments that are designated to allow us to test/evaluate the influence of one or more variables present in a given corrosion reaction; for example, the application of anodic protection to control the corrosion of bare steel in concentrated sulfuric acid (see the subsection "Anodic Protection" earlier in Sec. 25). The AP system is designed to introduce an applied electrical current, that is, purposely "making" the steel surface the anode, making it corrode, and then taking advantage of its resultant electrochemical reaction to control that corroding surface into a condition with an extremely low rate of corrosion. We had earlier suggested that those electrochemists very well schooled and experienced in their trade also understand the major limitations of many of these types of techniques in real-life situations. Professor Scully, in the *ASTM Manual* referenced above, included a separate section addressing these limitations. An applicable example is the limitations to the general use of AC and EIS test techniques, for the study of corrosion systems. AC and EIS techniques are applicable for the evaluation of very thin films or deposits that are uniform, constant, and stable—for example, thin-film protective coatings. Sometimes, researchers do not recognize the dynamic nature of some passive films, corrosion products, or deposits from other sources; nor do they even consider the *possibility of a change* in the surface conditions during the course of their experiment. As an example, it is noteworthy that this is a *major* potential problem in the electrochemical evaluation of microbiological corrosion (MIC).

MIC depends on the complex structure of corrosion products and passive films on metal surfaces as well as on the structure of the biofilm. Unfortunately, electrochemical methods have sometimes been used in complex electrolytes, such as microbiological culture media, where the characteristics and properties of passive films and MIC deposits are *quite active* and not fully understood. It must be kept in mind that microbial colonization of passive metals can drastically change their resistance to film breakdown by causing *localized* changes in the type, concentration, and thickness of anions, pH, oxygen gradients, and inhibitor levels at the metal surface during the course of a

normal test; viable single-cell microorganisms divide at an exponential rate. These changes can be expected to result in important modifications in the electrochemical behavior of the metal and, accordingly, in the electrochemical parameter measured in laboratory experiments.

Warnings are noted in the literature to be careful in the *interpretation* of data from electrochemical techniques applied to systems in which complex and often poorly understood effects are derived from surfaces which contain *active* or *viable* organisms, and so forth. Rather, it is even more important to not use such test protocol unless the investigator fully understands both the corrosion mechanism and the test technique being considered—and their interrelationship.

## CORROSION TESTING: PLANT TESTS

It is not always practical or convenient to investigate corrosion problems in the laboratory. In many instances, it is difficult to discover just what the conditions of service are and to reproduce them exactly. This is especially true with processes involving changes in the composition and other characteristics of the solutions as the process is carried out, as, for example, in evaporation, distillation, polymerization, sulfonation, or synthesis.

With many natural substances also, the exact nature of the corrosive is uncertain and is subject to changes not readily controlled in the laboratory. In other cases, the corrosiveness of the solution may be influenced greatly by or even may be due principally to a constituent present in such minute proportions that the mass available in the limited volume of corrosive solution that could be used in a laboratory setup would be exhausted by the corrosion reaction early in the test, and consequently the results over a longer period of time would be misleading.

Another difficulty sometimes encountered in laboratory tests is that contamination of the testing solution by corrosion products may change its corrosive nature to an appreciable extent.

In such cases, it is usually preferable to carry out the corrosion-testing program by exposing specimens in operating equipment under **actual conditions of service**. This procedure has the additional advantages that it is possible to test a large number of specimens at the same time and that little technical supervision is required.

In certain cases, it is necessary to choose materials for equipment to be used in a process developed in the laboratory and not yet in operation on a plant scale. Under such circumstances, it is obviously impossible to make plant tests. A good procedure in such cases is to construct a pilot plant, using either the cheapest materials available or some other materials selected on the basis of past experience or of laboratory tests. While the pilot plant is being operated to check on the process itself, specimens can be exposed in the operating equipment as a guide to the choice of materials for the large-scale plant or as a means of confirming the suitability of the materials chosen for the pilot plant.

**Test Specimens** In carrying out plant tests it is necessary to install the test specimens so that they will not come into contact with other metals and alloys; this avoids having their normal behavior disturbed by galvanic effects. It is also desirable to protect the specimens from possible mechanical damage.

There is no single standard size or shape for corrosion-test coupons. They usually weigh from 10 to 50 g and preferably have a large surface-to-mass ratio. Disks 40 mm (1½ in) in diameter by 3.2 mm (¼ in) thick and similarly dimensioned square and rectangular coupons are the most common. Surface preparation varies with the aim of the test, but machine grinding of surfaces or polishing with a No. 120 grit is common. Samples should not have sheared edges, should be clean (no heat-treatment scale remaining unless this is specifically part of the test), and should be identified by stamping. See Fig. 25-18 for a typical plant test assembly.

The choice of materials from which to make the holder is important. Materials must be durable enough to ensure satisfactory completion of the test. It is good practice to select very resistant materials for the test assembly. Insulating materials used are plastics, porcelain, Teflon, and glass. A phenolic plastic answers most purposes; its principal limitations are unsuitability for use at temperatures over 150°C (300°F) and lack of adequate resistance to concentrated alkalis.

FIG. 25-18 Assembly of a corrosion-test spool and specimens. (Mantell, ed., Engineering Materials Handbook, McGraw-Hill, New York, 1958.)

The method of supporting the specimen holder during the test period is important. The preferred position is with the long axis of the holder horizontal, thus avoiding dripping of corrosion products from one specimen to another. The holder must be located so as to cover the conditions of exposure to be studied. It may have to be submerged, or exposed only to the vapors, or located at liquid level, or holders may be called for at all three locations. Various means have been utilized for supporting the holders in liquids or in vapors. The simplest is to suspend the holder by means of a heavy wire or light metal chain. Holders have been strung between heating coils, clamped to agitator shafts, welded to evaporator tube sheets, and so on. The best method is to use test racks.

In a few special cases, the standard "spool-type" specimen holder is not applicable and a suitable special test method must be devised to apply to the corrosion conditions being studied.

For conducting tests in **pipe lines** of 75-mm (3-in) diameter or larger, a spool holder as shown in Fig. 25-19, which employs the same disk-type specimens used on the standard spool holder, has been used. This frame is so designed that it may be placed in a pipe line in any position without permitting the disk specimens to touch the wall of the pipe. As with the strip-type holder, this assembly does not materially interfere with the fluid through the pipe and permits the study of corrosion effects prevailing in the pipe line.

Another way to study corrosion in pipe lines is to install in the line short sections of pipe of the materials to be tested. These test sections should be insulated from each other and from the rest of the piping

FIG. 25-19 Spool-type specimen holder for use in 3-in-diameter or larger pipe. (Mantell, ed., Engineering Materials Handbook, McGraw-Hill, New York, 1958.)

FIG. 25-20 Methods for attaching specimens to test racks and to parts of moving equipment. (Mantell, ed., Engineering Materials Handbook, McGraw-Hill, New York, 1958.)

system by means of nonmetallic couplings. It is also good practice to provide insulating gaskets between the ends of the pipe specimens where they meet inside the couplings. Such joints may be sealed with various types of dope or cement. It is desirable in such cases to paint the outside of the specimens so as to confine corrosion to the inner surface.

It is occasionally desirable to expose corrosion-test specimens in operating equipment without the use of specimen holders of the type described. This can be accomplished by attaching specimens directly to some part of the operating equipment and by providing the necessary insulation against galvanic effects as shown in Fig. 25-20. The suggested method of attaching specimens to racks has been found to be very suitable in connection with the exposure of specimens to corrosion in seawater.

**Test Results** The methods of cleaning specimens and evaluating results after plant corrosion tests are identical to those described earlier for laboratory tests.

**Electrochemical On-Line Corrosion Monitoring\*** On-line corrosion monitoring is used to evaluate the status of equipment and piping in chemical process industries (CPI) plants. These monitoring methods are based on electrochemical techniques. To use on-line monitoring effectively, the engineer needs to understand the underlying electrochemical test methods to be employed. This section covers many of these test methods and their applications as well as a review of potential problems encountered with such test instruments and how to overcome or avoid these difficulties.

**Most Common Types of Probes** There are three most common types of corrosion monitoring probes used. Other types of probes are used, but in smaller numbers.

1. **Weight loss probes.** Coupons for measuring weight loss are still the primary type of probe in use. These may be as simple as samples of the process plant materials which have been fitted with electrical connections and readouts to determine intervals for retrieval and weighing, to commercially available coupons of specified material, geometry, stress condition, and other factors, ready to be mounted on specially designed supports at critical points in the process. Coupons can be permanently installed prior to plant start-up or during a shutdown. This type of permanent installation requires a plant shutdown for probe retrieval as well. Shutdown can be avoided by installing the probe in a bypass. Weight loss measurements do not accurately measure the severity of pitting corrosion, including that due to MIC.

2. **Electrical resistance probes.** These probes are the next most common type of corrosion probes after coupons. This type of probe measures changes in the electrical resistance as a thin strip of metal gets

\*Excerpted from papers by Oliver W. Siebert, courtesy of NACE International and ASTM.

thinner with ongoing corrosion. As the metal gets thinner, its resistance increases. This technique was developed in the 1950s by Draviniaks and Cataldi and has undergone many improvements since then.

3. *Linear polarization resistance probes.* LPR probes are more recent in origin, and are steadily gaining in use. These probes work on a principle outlined in an ASTM guide on making polarization resistance measurements, providing instantaneous corrosion rate measurements (G59, "Standard Practice for Conducting Potentiodynamic Polarization Resistance Measurements").

LPR probes measure the electrochemical corrosion mechanism involved in the interaction of the metal with the electrolyte. To measure linear polarization resistance  $R_p$ ,  $\Omega/\text{cm}^2$ , the following assumptions must be made:

- The corrosion rate is uniform.
- There is only cathodic and one anodic reaction.
- The corrosion potential is not near the oxidation/reduction potential for either reaction.

When these conditions are met, the current density associated with a small polarization of the metal (less than +10 mV) is directly proportional to the corrosion rate of the metal.

**Multiinformational Probes** Corrosion probes can provide more information than just corrosion rate. The next three types of probes yield information about the type of corrosion, the kinetics of the corrosion reaction, as well as the local corrosion rate.

*Electrochemical impedance spectroscopy, AC probes.* EIS, although around since the 1960s, has primarily been a laboratory technique. Commercially available probes and monitoring systems that measure EIS are becoming more widely used, especially in plants that have on-staff corrosion experts to interpret the data or to train plant personnel to do so.

In EIS, a potential is applied across a corroding metal in solution, causing current to flow. The amount of current depends upon the corrosion reaction on the metal surface and the flow of ions in solution. If the potential is applied as a sine wave, it will cause harmonics of the current output. The relationship between the applied potential and current output is the impedance, which is analogous to resistance in a DC circuit.

Since the potential and current are sinusoidal, the impedance has a magnitude and a phase, which can be represented as a vector. A sinusoidal potential or current can be pictured as a rotating vector. For standard AC current, the rotation is at a constant angular velocity of 60 Hz.

The voltage can also be pictured as a rotating vector with its own amplitude and frequency. Both current and potential can be represented as having real (observed) and imaginary (not observed) components.

In making electrochemical impedance measurements, one vector is examined, using the others as the frame of reference. The voltage vector is divided by the current vector, as in Ohm's law. Electrochemical impedance measures the impedance of an electrochemical system and then mathematically models the response using simple circuit elements such as resistors, capacitors, and inductors. In some cases, the circuit elements are used to yield information about the kinetics of the corrosion process.

*Polarization probes.* Polarization methods other than LPR are also of use in process control and corrosion analysis, but only a few systems are offered commercially. These systems use such polarization techniques as galvanodynamic or potentiodynamic, potentiostatic or galvanostatic, potentiostaircase or galvanostaircase, or cyclic polarization methods. Some systems involving these techniques are, in fact, used regularly in processing plants. These methods are used in situ or in the laboratory to measure corrosion. Polarization probes have been successful in reducing corrosion-related failures in chemical plants.

Polarization probes rely on the relationship of the applied potential to the output current per unit area (current density). The slope of applied potential versus current density, extrapolated through the origin, yields the polarization resistance  $R_p$ , which can be related to the corrosion rate.

There are several methods for relating the corrosion current, the applied potential, and the polarization resistance. These methods involve various ways of stepping or ramping either the potential or current. Also, a constant value of potential or current can be applied.

*Electrochemical noise monitoring probes.* Electrochemical noise monitoring is probably the newest of these methods. The method characterizes the naturally occurring fluctuations in current and potential due to the electrochemical kinetics and the mechanism of

the corroding metal interface. Measurements are taken without perturbing the interface by applying a potential or current to it. In this way, electrochemical processes are not interrupted and the system is measured without being disturbed. Methods including signal processing and mathematical transformation are used to provide information on the reaction kinetics at the surface and the corrosion rate.

This technique, originally discovered in the 1960s, remained a laboratory technique until recently, when some manufacturers began producing commercial devices. There are a few cases where electrochemical noise is being used in process-plant-type environments, and an ASTM committee has been formed to look at standardization of this technique. However, in general it remains a laboratory method with great potential for on-line monitoring. Recent research has demonstrated that electrochemical noise can be used to monitor MIC under laboratory conditions when appropriate probe configurations are used. Tests of these techniques in actual operating environments have been limited.

**Indirect Probes** Some types of probes do not measure corrosion directly, but yield measurements that also are useful in detecting corrosion. Examples include:

*Pressure probes.* Pressure monitors or transducers may be of use in corrosion monitoring in environments where buildup of gases such as hydrogen or  $\text{H}_2\text{S}$  may contribute to corrosion.

*Gas probes.* The hydrogen patch probe allows users to determine the concentration of hydrogen in the system. This is an important measurement since hydrogen can foster corrosion. Detecting production of certain gases may give rise to process changes to eliminate or limit the gaseous effluent and, therefore, lower the possibility of corrosion caused by these gases.

*pH probes.* Monitoring the pH may also aid in the early detection of corrosion. The acidity or alkalinity of the environment is often one of the controllable parameters in corrosion. Monitoring of the pH can be combined with other corrosion measurements to provide additional data about process conditions and give another level of process control.

*Ion probes.* Determining the level of ions in solution also helps to control corrosion. An increase in concentration of specific ions can contribute to scale formation, which can lead to a corrosion-related failure. Ion-selective electrode measurements can be included, just as pH measurements can, along with other more typical corrosion measurements. Especially in a complete monitoring system, this can add information about the effect of these ions on the material of interest at the process plant conditions.

*Microbially influenced corrosion (MIC) probes.* Devices are available which it is claimed can be used to measure the amount of microbial activity in some environments. Most of these "MIC monitoring devices" are limited in their application. The major problem lies in proving that the corrosion being detected is due to MIC. This is an exciting area for development of corrosion probes and monitoring systems.

**Use of Corrosion Probes** The major use of corrosion monitoring probes is to measure the corrosion rate in the plant or the field. In addition to corrosion-rate measurements, corrosion probes can be used to detect process upsets that may change the corrosion resistance of the equipment of interest. This is usually equally as important a measurement as corrosion rate since a change in the process conditions can lead to dramatic changes in the corrosion rate.

If the upset can be detected and dealt with in short order, the system can be protected. Some of the probes that measure parameters such as pH, ion content, and others are sensitive to process upsets and may give the fastest most complete information about such changes.

Monitoring can also be used to optimize the chemistry and level of corrosion inhibitors used. If too little inhibitor is used, enhanced corrosion can result and failure may follow. If too much is used, costs will increase without providing any additional protection. Optimization of the addition of inhibitor in terms of time, location in the process, and method of addition can also be evaluated through the use of carefully placed probes.

Another area where probes can be used effectively is in monitoring of deposits such as scale. One method of measurement is detecting specific ions that contribute to scale buildup or fouling; another is measuring the actual layers. Scale and fouling often devastate the corrosion resistance of a system, leading to a costly corrosion-related plant shutdown.

A final type of measurement is the detection of localized corrosion, such as pitting or crevice attack. Several corrosion-measuring probes can be used to detect localized corrosion. Some can detect localized corrosion instantaneously and others only its result. These types of corrosion may contribute little to the actual mass loss, but can be devastating to equipment and piping. Detection and measurement of localized corrosion is one of the areas with the greatest potential for the use of some of the newest electrochemically based corrosion monitoring probes.

**Corrosion Rate Measurements** Determining a corrosion rate from measured parameters (such as mass loss, current, or electrical potential) depends on converting the measurements into a corrosion rate by use of relationships such as Faraday's law.

Information on the process reaction conditions may be important to prolonging the lifetime of process equipment. Techniques such as EIS and potentiodynamic polarization can provide just such information without being tied to a specific corrosion-rate measurement.

This is also the case with methods that yield information on localized corrosion. The overall corrosion rate may be small when localized attack occurs, but failure due to perforation or loss of function may be the consequence of localized attack.

**Measuring Corrosion Rate with Coupons** Corrosion rate determined with typical coupon tests is an average value, averaged over the entire life of the test. Changes in the conditions under which the coupons are tested are averaged over the time the coupon is exposed. *Uniform attack is assumed to occur.* Converting measured values of loss of mass into an average corrosion rate has been covered extensively by many authors, and standard practices exist for determining corrosion rate.

Corrosion rates may vary during testing. Since the rate obtained from coupon testing is averaged over time, the frequency of sampling is important. Generally, measurements made over longer times are more valid. This is especially true for low corrosion rates, under 1 mil/y, mpy (0.001 in/y). When corrosion rates are this low, longer times should be used.

Factors may throw off these rates—these are outlined in ASTM G31, "Standard Practice for Laboratory Immersion Corrosion Testing of Metals." Coupon-type tests cannot be correlated with changing plant conditions that may dramatically affect process equipment lifetimes. Other methods must be used if more frequent measurements are desired or correlation with plant conditions is necessary.

A plot of mass loss versus time can provide information about changes in the conditions under which the test has been run. One example of such a plot comes from the ASTM Standard G96, "Standard Guide." As mentioned previously, weight loss measurements are appropriate for measurement of localized pitting corrosion, including that caused by MIC.

**Heat Flux Tests** Removable tube test heat exchangers find an ideal use in the field for monitoring heat flux (corrosion) conditions, NACE TMO286-94 (similar to laboratory test, Fig. 25-6).

The assumption of uniform corrosion is also at the heart of the measurements made by the electrical resistance (ER) probes. Again, ASTM Standard G96 outlines the method for using ER probes in plant equipment. These probes operate on the principle that the electrical resistance of a wire, strip, or tube of metal increases as its cross-sectional area decreases:

$$R = \frac{\rho L}{A}$$

where  $R$  = resistance,  $\Omega$   
 $\rho$  = resistivity,  $\Omega/\text{cm}$   
 $L$  = length, cm  
 $A$  = cross-sectional area,  $\text{cm}^2$

Usually, in practice, the resistance is measured as a ratio between the actual measuring element and a similar element protected from the corrosive environment (the reference), and is given by  $R_M/R_R$  where subscript  $M$  is for measured and  $R$  is for reference.

Measurements are recorded intermittently or continuously. Changes in the slope of the curve obtained thus yields the corrosion rate.

The initial measurement of electrical resistance must be made after considerable time. Phenomenological information has been determined based on the corrosion rate expected at what period of time to initiate readings of the electrical resistance. Since these values are

based on experiential factors rather than on fundamental (so-called *first*) principles, correlation tables and lists of suggested thicknesses, compositions, and response times for usage of ER-type probes have developed over time, and these have been incorporated into the values read out of monitoring systems using the ER method.

**Electrochemical Measurement of Corrosion Rate** There is a link between electrochemical parameters and actual corrosion rates. Probes have been specifically designed to yield signals that will provide this information. LPR, ER, and EIS probes can give corrosion rates directly from electrochemical measurements. ASTM G102, "Standard Practice for Calculation of Corrosion Rates and Related Information from Electrochemical Measurements," tells how to obtain corrosion rates directly. Background on the approximations made in making use of the electrochemical measurements has been outlined by several authors.

ASTM G59, "Standard Practice for Conducting Potentiodynamic Polarization Resistance Measurements," provides instructions for the graphical plotting of data (from tests conducted using the above-noted ASTM Standard G103) as the linear potential versus current density, from which the polarization resistance can be found.

Measurements of polarization resistance  $R_p$ , given by LPR probes, can lead to measurement of the corrosion rate at a specific instant, since values of  $R_p$  are instantaneous.

To obtain the corrosion current  $I_{\text{corr}}$  from  $R_p$ , values for the anodic and cathodic slopes must be known or estimated. ASTM G59 provides an experimental procedure for measuring  $R_p$ . A discussion of the factors which may lead to errors in the values for  $R_p$ , and cases where  $R_p$  technique cannot be used, are covered by Mansfield in "Polarization Resistance Measurements—Today's Status, Electrochemical Techniques for Corrosion Engineers" (NACE International, 1992).

Some data from corrosion-monitoring probes do not measure corrosion rate, but rather give other useful information about the system. For example, suppose conditions change dramatically during a process upset. An experienced corrosion engineer can examine the data and correlate it with the upset conditions. Such analysis can provide insight into the process and help to improve performance and extend equipment lifetime. Changes in simple parameters such as pH, ion content, and temperature may lead to detection of a process upset. Without careful analysis, process upsets can reduce the corrosion lifetime of equipment and even cause a system failure.

Analysis of biological activity is sometimes difficult to correlate to corrosion rates. However, with detection and correlation of microbiological processes, especially those known to be related to corrosion (e.g., respiration rates, amount of acidity being produced) with process conditions, such information may also lead to improvements in the corrosion lifetime of the process equipment.

Evidence of localized corrosion can be obtained from polarization methods such as potentiodynamic polarization, EIS, and electrochemical noise measurements, which are particularly well suited to providing data on localized corrosion. When evidence of localized attack is obtained, the engineer needs to perform a careful analysis of the conditions that may lead to such attack. Correlation with process conditions can provide additional data about the susceptibility of the equipment to localized attack and can potentially help prevent failures due to pitting or crevice corrosion. Since pitting may have a delayed initiation phase, careful consideration of the cause of the localized attack is critical. Laboratory testing and involvement of an experienced corrosion engineer may be needed to understand the initiation of localized corrosion. Theoretical constructs such as Pourbaix diagrams can be useful in interpreting data obtained by on-line monitors.

Combinations of several types of probes can improve the information concerning corrosion of the system. Using only probes that provide corrosion-rate data cannot lead to as complete an analysis of the process and its effect on the equipment as with monitoring probes, which provide additional information.

**Other Useful Information Obtained by Probes** Both EIS and electrochemical noise probes can be used to determine information about the reactions that affect corrosion. Equivalent circuit analysis, when properly applied by an experienced engineer, can often give insight into the specifics of the corrosion reactions. Information such as corrosion product layer buildup, or inhibitor effectiveness, or coating breakdown can be obtained directly from analysis of the data from EIS or

indirectly from electrochemical noise data. In most cases, this is merely making use of methodology developed in the corrosion laboratory.

Some assumptions must be made to do this, but these assumptions are no different from those made in the laboratory. Recent experience involving in-plant usage of EIS has shown that this technique can be used effectively as a monitoring method and has led to development of several commercial systems.

Making use of the information from monitoring probes, combined with the storage and analysis capabilities of portable computers and microprocessors, seems the best method for understanding corrosion processes. Commercial setups can be assembled from standard probes, cables, readout devices, and storage systems. When these are coupled with analysis by corrosion engineers, the system can lead to a better understanding of in-plant corrosion processes.

**Limitations of Probes and Monitoring Systems** There are limitations even with the most up-to-date systems. Some of the things which cannot be determined using corrosion probes include:

*Specifics on the types and rates of microbiological attack.* These must be determined by using other methods such as chemical and microbiological analysis of the solution and materials from the corrosion sites. Consideration must be given to limitations of electrochemical techniques for MIC studies, noted previously under "Corrosion Testing: Laboratory Tests" and subsequent subsections.

*Actual lifetime of the plant equipment.* Corrosion monitoring provides data, which must then be analyzed with additional input and interpretation. However, only estimates can be made of the lifetime of the equipment of concern. Lifetime predictions are, at best, carefully crafted guesses based on the best available data.

*Choices of alternative materials.* Corrosion probes are carefully chosen to be as close as possible to the alloy composition, heat treatment, and stress condition of the material that is being monitored. Care must be taken to ensure that the environment at the probe matches the service environment. Choices of other alloys or heat treatments and other conditions must be made by comparison. Laboratory testing or coupon testing in the process stream can be used to examine alternatives to the current material, but the probes and the monitors can only provide information about the conditions which are present during the test exposure and cannot extrapolate beyond those conditions.

*Failure analysis.* Often, for a corrosion-related failure, data from the probes are examined to look for telltale signs that could have led to detection of the failure. In some cases, evidence can be found that process changes were occurring which led to the failure. This does not mean that the probes should have detected the failure itself. Determination of an imminent corrosion-related failure is not possible, even with the most advanced monitoring system.

The aforementioned limitations are not problems with the probes or the monitoring systems but occur when information is desired that cannot be measured directly or which requires extrapolation. Many of the problems that are encountered with corrosion-monitoring systems and probes are related to the use to which probes are put.

**Potential Problems with Probe Usage** Understanding the electrochemical principles upon which probes are based helps to eliminate some of the potential problems with probes. However, in some situations, the information desired is not readily available.

For example, consider localized corrosion. Although data from corrosion probes indicate corrosion rate, it is not possible to tell that localized corrosion is the problem. It is certainly not possible to demonstrate the mechanisms responsible for the localized corrosion.

This is an example of measuring the wrong thing. In this case, the probes work adequately, the monitoring system is adequate, as is the monitoring interval, but detection of the type of corrosion cannot be made based on the available data. Different types of probes and testing are required to detect the corrosion problem.

Another problem can arise if the probes and monitors are working properly but the probe is placed improperly (this is very common in natural gas transmission pipelines). Then the probe does not measure the needed conditions and environment. The data obtained by the probe will not tell the whole story and can in fact give very misleading results.

An example of this is in a condenser where the corrosion probe is in a region where the temperature is lower than that at the critical condition of interest. Local scale buildup is another example of this type of situation, as is formation of a crevice at a specific location.

The type of probe, its materials, and method of construction must be carefully considered in designing an effective corrosion-monitoring system. Since different types of probes provide different types of information, it may be necessary to use several types.

Incorrect information can result if the probe is made of the wrong material and is not heat treated in the same way as the process equipment (as well as because of other problems). The probe must be as close as possible to the material from which the equipment of interest is made. Existence of a critical condition, such as weldments or galvanic couples or occluded cells in the equipment of concern, makes the fabrication, placement, and maintenance of the probes and monitoring system of critical importance, if accurate and useful data are to be obtained.

Before electrochemical techniques are used in the evaluation of any situation involving microbes, the test protocol must receive considerable review by personnel quite experienced in *both* electrochemical testing and microbiologically influenced corrosion. It must be demonstrated that the method is capable of detecting and in some cases quantitatively measuring corrosion influenced by microbes.

The data obtained from probes and monitoring systems are most useful when analyzed by a corrosion specialist. Data not taken, analyses not made, or expertise not sought can quickly lead to problems even with the most up-to-date corrosion probes and monitoring system.

## ECONOMICS IN MATERIALS SELECTION

In most instances, there will be more than one alternative material which may be considered for a specific application. Calculation of true long-term costs requires estimation of the following:

1. Total cost of fabricated equipment and piping
2. Total installation cost
3. Service life
4. Maintenance costs: amount and timing
5. Time and cost requirements to replace or repair at the end of service life
6. Cost of downtime to replace or repair
7. Cost of inhibitors, extra control facilities, and so on, required to assure achievement of predicted service life
8. Time value of money
9. Factors which impact taxation, such as depreciation and tax rates
10. Inflation rate

Proper economic analysis will allow comparison of alternatives on a sound basis. Detailed calculations are beyond the scope of this section. The reader should review the material in the NACE Publication 3C194, Item No. 24182, "Economics of Corrosion," Sept., 1994.

## PROPERTIES OF MATERIALS

### MATERIALS STANDARDS AND SPECIFICATIONS

There are obvious benefits to be derived from consensus standards that define the chemistry and properties of specific materials. Such standards allow designers and users of materials to work with confidence that the materials supplied will have the expected minimum

properties. Designers and users can also be confident that comparable materials can be purchased from several suppliers. Producers are confident that materials produced to an accepted standard will find a ready market and therefore can be produced efficiently in large factories.

**TABLE 25-2 Unified Alloy Numbering System (UNS)**

UNS was established in 1974 by ASTM and SAE to reduce the confusion involved in the labeling of commercial alloys. Metals have been placed into 15 groups, each of which is given a code letter. The specific alloy is identified by a five-digit number following this code letter.

| Nonferrous metals and alloys |  |
|------------------------------|--|
| A00001–A99999                | Aluminum and aluminum alloys                     |
| C00001–C99999                | Copper and copper alloys                         |
| E00001–E99999                | Rare-earth and rare-earth-like metals and alloys |
| L00001–L99999                | Low-melting metals and alloys                    |
| M00001–M99999                | Miscellaneous nonferrous metals and alloys       |
| N00001–N99999                | Nickel and nickel alloys                         |
| P00001–P99999                | Precious metals and alloys                       |
| R00001–R99999                | Reactive and refractory metals and alloys        |
| Ferrous metals and alloys    |  |
| D00001–D99999                | Specified-mechanical-properties steels           |
| F00001–F99999                | Cast irons and cast steels                       |
| G00001–G99999                | AISI and SAE carbon and alloy steels             |
| H00001–H99999                | AISI H steels                                    |
| K00001–K99999                | Miscellaneous steels and ferrous alloys          |
| S00001–S99999                | Heat- and corrosion-resistant (stainless) steels |
| T00001–T99999                | Tool steels                                      |

When possible, earlier widely used three- or four-digit alloy numbering systems such as those developed by the Aluminum Association (AA), Copper Development Association (CDA), American Iron and Steel Institute (AISI), etc., have been incorporated by the addition of the appropriate alloy-group code letter plus additional digits. For example:

| Alloy description                | Former designation |      | UNS designation |
|----------------------------------|--------------------|------|-----------------|
|                                  | System             | No.  |                 |
| Aluminum + 1.2% Mn               | AA                 | 3003 | A93003          |
| Copper, electrolytic tough pitch | CDA                | 110  | C11000          |
| Carbon steel, 0.2% C             | AISI               | 1020 | G10200          |
| Stainless steel, 18 Cr, 8 Ni     | AISI               | 304  | S30400          |

Proprietary alloys are assigned numbers by the AA, AISI, CDA, ASTM, and SAE, which maintains master listings at their headquarters. Handbooks describing the system are available. (Cf. ASTM publication DS-56AC.)

While a detailed treatment is beyond the scope of this subsection, a few of the organizations which generate standards of major importance to the chemical-process industries in the United States are listed below. An excellent overview is presented in the *Encyclopedia of Chemical Technology* (5th ed., Wiley, Hoboken, N.J., 2006).

1. **American National Standards Institute (ANSI)**, formerly American Standards Association (ASA). ANSI promulgates the piping codes used in the chemical-process industries.

2. **American Society of Mechanical Engineers (ASME)**. This society generates the Boiler and Pressure Vessel Codes.

3. **American Society for Testing and Materials (ASTM)**. This society generates specifications for most of the materials used in the ANSI Piping Codes and the ASME Boiler and Pressure Vessel Codes.

4. **International Organization for Standardization (ISO)**. This organization is engaged in generating standards for worldwide use. It has 80 member nations.

With only a few noticeable exceptions, metals and their alloys possess a distinct shape. To generate the principal shape, metals are said to be **wrought** or **cast**. Wrought metals receive their shape through deformation steps; cast metals receive their shape through solidification steps. Materials of construction are available in both wrought and cast forms. Each group is discussed separately.

**WROUGHT MATERIALS: FERROUS METALS AND ALLOYS**

**Steel** Carbon steel is the most common, least expensive, and most versatile metal used in industry. It has excellent ductility, permitting many cold-forming operations. Steel is also very weldable. The grades of steel most commonly used in the chemical-process industries have tensile strength in the 345- to 485-MPa (50,000 to

70,000 lbf/in<sup>2</sup>) range, with good ductility. Higher strength levels are achieved by cold work, alloying, and heat treatment.

Carbon steel is easily the most commonly used material in process plants despite its somewhat limited corrosion resistance. It is routinely used for most organic chemicals and neutral or basic aqueous solutions at moderate temperatures. It is also used routinely for the storage of concentrated sulfuric acid and caustic soda [up to 50 percent and 55°C (130°F)]. Because of its availability, low cost, and ease of fabrication, steel is frequently used in services with corrosion rates of 0.13 to 0.5 mm/yr (5 to 20 mils/yr), with added thickness (**corrosion allowance**) to ensure the achievement of desired service life. Product quality requirements must be considered in such cases.

Corrosion under insulation is a major problem with carbon steels and must be taken into consideration in the RBI analysis of any plant to avoid serious failures. Several techniques are available to minimize this attack including painting, spraying with aluminum, and/or wrapping with aluminum foil.

**Low-Alloy Steels** Alloy steels contain one or more alloying agents to improve the mechanical and corrosion-resistant properties over those of carbon steel. A typical low-alloy grade [American Iron and Steel Institute (AISI) 4340] contains 0.40 percent C, 0.70 percent Mn, 1.85 percent Ni, 0.80 percent Cr, and 0.25 percent Mo. Many other alloying agents are used to produce a large number of standard AISI and proprietary grades. Nickel increases toughness and improves low-temperature properties and corrosion resistance. Chromium and silicon improve hardness, abrasion resistance, corrosion resistance, and resistance to oxidation. Molybdenum provides strength at elevated temperatures. The addition of small amounts of alloying materials greatly improves corrosion resistance to atmospheric environments but does not have much effect against liquid corrosives. The alloying elements produce a tight, dense, adherent rust film, but in acid or alkaline solutions corrosion is about equivalent to that of carbon steel. However, the greater strength permits thinner walls in process equipment made from low-alloy steel.

**Stainless Steel** There are more than 70 standard types of stainless steel and many special alloys. These steels are produced in the wrought form (AISI types) and as cast alloys [Alloy Casting Institute (ACI) types]. Generally, all are iron-based, with 12 to 30 percent chromium, 0 to 22 percent nickel, and minor amounts of carbon, niobium (columbium), copper, molybdenum, selenium, tantalum, and titanium. These alloys are very popular in the process industries. They are heat- and corrosion-resistant, noncontaminating, and easily fabricated into complex shapes.

There are four groups of stainless alloys: (1) martensitic, (2) ferritic, (3) austenitic, and (4) duplex.

The **martensitic alloys** contain 12 to 20 percent chromium with controlled amounts of carbon and other additives. Type 410 is a typical member of this group. These alloys can be hardened by heat treatment, which can increase tensile strength from 550 to 1380 MPa (80,000 to 200,000 lbf/in<sup>2</sup>). Corrosion resistance is inferior to that of austenitic stainless steels, and martensitic steels are generally used in mildly corrosive environments (atmospheric, freshwater, and organic exposures). In the hardened condition, these materials are very susceptible to hydrogen embrittlement.

**Ferritic stainless steel** contains 15 to 30 percent Cr, with low carbon content (0.1 percent). The higher chromium content improves its corrosive resistance. Type 430 is a typical example. The strength of ferritic stainless can be increased by cold working but not by heat treatment. Fairly ductile ferritic grades can be fabricated by all standard methods. They are fairly easy to machine. Welding is not a problem, although it requires skilled operators. Corrosion resistance is rated good, although ferritic alloys are not good against reducing acids such as HCl. But mildly corrosive solutions and oxidizing media are handled without harm. Type 430 is widely used in nitric acid plants. In addition, it is very resistant to scaling and high-temperature oxidation up to 800°C (1500°F).

**Austenitic stainless steels** are the most corrosion-resistant of the four groups. These steels contain 16 to 26 percent chromium and 6 to 22 percent nickel. Carbon is typically kept low (0.03 percent maximum) to minimize carbide precipitation. These alloys can be work-hardened, but heat treatment will not cause hardening. Tensile strength in the annealed condition is about 585 MPa (85,000 lbf/in<sup>2</sup>), but work hardening can increase this to 2000 MPa (300,000 lbf/in<sup>2</sup>) by creating martensite in the matrix. Austenitic stainless steels are tough and ductile. They can be fabricated by all standard methods. But austenitic grades are not easy to machine; they work-harden and gall. Rigid machines, heavy cuts, and low speeds are essential. Welding, however, is readily performed, although welding heat may cause chromium carbide precipitation, which depletes the alloy of some chromium and lowers its corrosion resistance in some specific environments, notably nitric acid. The carbide precipitation can be eliminated by heat treatment (solution annealing). To avoid precipitation, special stainless steels stabilized with titanium, niobium, or tantalum have been developed (types 321 and 347). The addition of molybdenum to the austenitic alloy (types 316, 316L, 317, and 317L) provides generally better corrosion resistance and improved resistance to pitting. Nitrogen additions have also shown benefit in improving localized corrosion resistance. Nitrogen also increases the strength, and materials today are frequently dual-certified, i.e., 304/304L but with a carbon content equal to a 304L.

In the stainless group, nickel greatly improves corrosion resistance over straight chromium stainless. Even so, the chromium-nickel steels, particularly the 18-8 alloys, perform best under **oxidizing conditions**, since resistance depends on an oxide film on the surface of the alloy. Reducing conditions and chloride ions destroy this film and

<sup>a</sup>Properties are for materials hardened and tempered as follows: <sup>b</sup>water-quenched from 1,525°F, tempered at 1,000°F; <sup>c</sup>oil-quenched from 1,525°F, tempered at 1,000°F; <sup>d</sup>pseudocarbonized 8 h at 1700°F, oil-quenched, tempered 1 h at 300°F; <sup>e</sup>water-quenched from 1,525°F, tempered at 600°F; <sup>f</sup>oil-quenched from 1,500°F, tempered at 600°F; <sup>g</sup>oil-quenched from 1,475°F, tempered at 600°F; <sup>h</sup>oil-quenched from 1,450°F, tempered at 600°F; <sup>i</sup>water-quenched from 1,500 to 1,600°F, tempered at 800°F; <sup>j</sup>oil-quenched from 1,550°F, tempered at 800°F; <sup>k</sup>oil-quenched from 1,525°F, tempered at 800°F; <sup>l</sup>normalized at 1,650°F, reheated to 1,475°F, oil-quenched, tempered at 800°F; <sup>m</sup>normalized at 1,625°F, reheated to 1,550°F, water-quenched, tempered at 800°F; <sup>n</sup>carburized 10 h at 1,680°F, pot-cooled, oil-quenched from 1,525°F, tempered at 300°F; <sup>o</sup>normalized at 1,600°F, oil-quenched from 1,575°F, tempered at 1,000°F; <sup>p</sup>oil-quenched tempered at 800°F; <sup>q</sup>normalized at 1,650°F, reheated to 1,625°F, quenched in agitated oil, tempered at 800°F; <sup>r</sup>normalized at 1,600°F, reheated to 1,575°F, quenched in agitated oil, tempered at 800°F.

NOTE: °C = (°F – 32) × 5/9. To convert Btu/(h-ft<sup>2</sup>·°F) to W/(m<sup>2</sup>·°C), multiply by 0.8666; to convert Btu/(lb·°F) to kJ/(kg·°C), multiply by 0.2388; to convert lbf/in<sup>2</sup> to MPa, multiply by 0.006895; and to convert ft-lbf to J, multiply by 0.7375.

bring on rapid attack. Chloride ions tend to cause pitting and crevice corrosion; when combined with high tensile stresses, they can cause stress-corrosion cracking.

A specialty group of alloys has been created with chromium and molybdenum significantly above the standard stainless grades. Many of these grades are proprietary and contain chromium of 20 percent and molybdenum of 6 to 7 percent, and most also contain nitrogen to

To convert MPa to lbf/in<sup>2</sup>, multiply by 145.04.

<sup>†</sup>Single values are maximum values.

<sup>‡</sup>Typical room-temperature properties.

improve localized corrosion resistance. This family is collectively known as the **6Mo family** and has corrosion resistance intermediate between the standard grades and some of the nickel-based alloys. They also have improved stress corrosion and localized corrosion resistance. Typical of this family are Avesta 254 SMO and Allegheny AL6XN.

**Duplex stainless** steels were created by adjusting the composition so that approximately equal amounts of the austenitic phase and the ferritic phase are present in the alloy. Three general families of alloys have been developed that contain 18 percent Cr, 22 percent Cr, and 25 percent Cr. As the chromium content increases, so does the general resistance of the alloys. All duplex alloys have better stress-corrosion resistance than the austenitic grades while the general corrosion resistance is not significantly increased. Because the structure is a mixture of ferritic and austenitic grains, the yield strength of this class of materials is significantly higher than that for the austenitic grades. Some of the “super duplex” (25 Cr) alloys have been used in offshore oil platforms because

of their strength and corrosion resistance, and they are finding increasing uses in chemical plants. These alloys suffer from a 474°C (885°F) embrittlement and so have lower maximum-use temperatures than the austenitic alloys. The presence of sigma phase in the microstructure can cause serious corrosion and mechanical problems. ASTM A 923 was developed to assist in determining the presence of sigma phase.

### WROUGHT MATERIALS: NONFERROUS METALS AND ALLOYS

**Nickel and Nickel Alloys** Nickel is available in practically any mill form as well as in castings. It can be machined easily and joined by welding. Generally, oxidizing conditions favor corrosion, while reducing conditions retard attack. Neutral alkaline solutions, seawater, and mild atmospheric conditions do not affect nickel. The metal is widely used for

 ¶Minimum.

handling alkalis, particularly in concentrating, storing, and shipping high-purity caustic soda. Chlorinated solvents and phenol are often refined and stored in nickel to prevent product discoloration and contamination. A large number of nickel-based alloys are commercially available.

One of the best known of these is **Monel 400**, 67 percent Ni and 30 percent Cu. It is available in all standard forms. This nickel-copper alloy is ductile and tough and can be readily fabricated and joined. Its corrosion resistance is generally superior to that of its components, being more resistant than nickel in reducing environments and more resistant than copper in oxidizing environments. The alloy can be used for relatively dilute sulfuric acid (below 80 percent), although aeration will result in increased corrosion. Monel will handle hydrofluoric acid up to 92 percent and 115°C (235°F) although aeration can produce cracking. Alkalies have little effect on this alloy, but it will not stand up against very highly oxidizing or reducing environments.

Another important alloy is a Ni-Mo alloy, **Hastelloy alloy B-3**. This alloy is 74 percent nickel and 26 percent molybdenum. The alloy is resistant to all hydrochloric acid solutions and other strongly reducing acids. The addition of oxidizers such as ferric or cupric ions or oxygen will accelerate corrosion. Work hardening presents some fabrication difficulties, and machining is somewhat more difficult than for 316L stainless.

The addition of chromium forms a family of Ni-Cr-Mo alloys such as **Hastelloy alloys C-276, C-22, and C-2000**. These alloys contain 16 to 22 percent chromium and 13 to 16 percent molybdenum and are very resistant to a wide variety of chemical environments. They are considered resistant to stress-corrosion cracking and very resistant to localized corrosion in chloride-containing environments. These alloys are resistant to strong oxidizing solutions, such as wet chlorine and hypochlorite solutions. They are among only a few alloys that are completely resistant to seawater. The carbon contents are low enough that weld sensitization is not a problem during fabrication. These alloys are also more difficult to machine than stainless steel, but fabrication is essentially the same.

Replacing some of the nickel with iron produces a family of alloys with intermediate corrosion resistance between stainless steels and the Ni-Cr-Mo alloys. Alloys such as **Incoloy 825** and **Hastelloy G-3 and G-30** are in this family. Incoloy 825 has 40 percent Ni, 21 percent Cr, 3 percent Mo, and 2.25 percent Cu. Hastelloy G-3 contains 44 percent Ni, 22 percent Cr, 6.5 percent Mo, and 0.05 percent C maximum. These alloys have extensive applications in sulfuric acid systems. Because of their increased nickel and molybdenum contents they are more tolerant of chloride-ion contamination than are standard stainless steels. The nickel content decreases the risk of stress-corrosion cracking; molybdenum improves resistance to crevice corrosion and pitting. Many of the nickel-based alloys are proprietary and are covered by the following specifications:

1. Sheet and plate: ASTM B 333, B575
2. Bar: ASTM B 335, B 574
3. Forgings: ASTM B 564

4. Welded pipe and tubing: ASTM B 626, B 619
5. Seamless pipe and tubing: ASTM B 622
6. Fittings: ASTM B 366

All the nickel alloys are readily fabricated and welded. Their design strengths allow use to elevated temperatures and with relatively thin wall thicknesses. The Nickel Institute (<http://www.nickelinstitute.org>) has excellent publications available that detail the properties and fabrication requirements for both stainless steels and nickel-based alloys, as does SSINA (<http://www.ssina.com>) and so do many of the manufacturers of these alloys.

**Aluminum and Alloys** Aluminum and its alloys are made in practically all the forms in which metals are produced, including castings. Thermal conductivity of aluminum is 60 percent of that of pure copper, and unalloyed aluminum is used in many heat-transfer applications. Its high electrical conductivity makes aluminum popular in electrical applications. Aluminum is one of the most workable of metals, and it is usually joined by inert-gas-shielded arc-welding techniques.

**Commercially pure aluminum** has a tensile strength of 69 MPa (10,000 lbf/in<sup>2</sup>), but it can be strengthened by cold working. One limitation of aluminum is that strength declines greatly above 150°C (300°F). When strength is important, 200°C (400°F) is usually considered the highest permissible safe temperature for aluminum. However, aluminum has excellent low-temperature properties; it can be used at -250°C (-420°F). Aluminum has high resistance to atmospheric conditions as well as to industrial fumes and vapors and fresh, brackish, or salt waters. Many mineral acids attack aluminum, although the metal can be used with concentrated nitric acid (above 82 percent) and glacial acetic acid. Aluminum cannot be used with strong caustic solutions.

Note that a number of **aluminum alloys** are available (see Table 25-17). Many have improved mechanical properties over pure aluminum. The wrought heat-treatable aluminum alloys have tensile strengths of 90 to 228 MPa (13,000 to 33,000 lbf/in<sup>2</sup>) as annealed; when they are fully hardened, strengths can go as high as 572 MPa (83,000 lbf/in<sup>2</sup>). However, aluminum alloys usually have lower corrosion resistance than the pure metal.

The **Alclad** alloys have been developed to overcome this shortcoming. Alclad consists of a pure aluminum layer metallurgically bonded to a core alloy. The corrosion resistance of aluminum and its alloys tends to be very sensitive to trace contamination. Very small amounts of metallic mercury, heavy-metal ions, or chloride ions can frequently cause rapid failure under conditions which otherwise would be fully acceptable. When alloy steels do not give adequate corrosion protection—particularly from sulfidic attack—steel with an **aluminized surface coating** can be used.

A spray coating of aluminum on a steel is not likely to spall or flake, but the coating is usually not continuous and may leave some areas of the steel unprotected. Hot-dipped “aluminized” steel gives a continuous coating and has proved satisfactory in a number of applications,

particularly when sulfur or hydrogen sulfide is present. It is also used to protect thermal insulation and as weather shields for equipment. The coated steel resists fires better than solid aluminum.

**Copper and Alloys** Copper and its alloys are widely used in chemical processing, particularly when heat and electrical conductivity are important factors. The thermal conductivity of copper is twice that of aluminum and 90 percent that of silver. A large number of copper alloys are available, including brasses (Cu-Zn), bronzes (Cu-Sn), cupronickels (Cu-Ni), and age-hardenable alloys such as copper beryllium (Cu-Be) and copper nickel tin (Cu-Ni-Sn).

**Copper** has excellent low-temperature properties and is used at  $\sim 200^{\circ}\text{C}$  ( $\sim 320^{\circ}\text{F}$ ). Brazing and soldering are common joining methods for copper, although welding, while difficult, is possible. Generally, copper has high resistance to industrial and marine atmospheres, seawater, alkalis, and solvents. Oxidizing acids rapidly corrode copper. However, the alloys have somewhat different properties from those of commercial copper.

**Brasses** with up to 15 percent Zn are ductile but difficult to machine. Machinability improves with increasing zinc up to 36 percent Zn. Brasses with less than 20 percent Zn have corrosion resistance equivalent to that of copper but with better tensile strengths. Brasses with 20 to 40 percent Zn have lower corrosion resistance and are subject to dezincification and stress-corrosion cracking, especially when ammonia is present.

**Bronzes** are somewhat similar to brasses in mechanical properties and to high-zinc brasses in corrosion resistance (except that bronzes are not affected by stress cracking).

**Aluminum and silicon bronzes** are very popular in the process industries because they combine good strength with corrosion resistance. Copper-beryllium alloys offer the greatest strength and excellent corrosion resistance in seawater and are resistant to stress-corrosion cracking in hydrogen sulfide.

**Cupronickels** (10 to 30 percent Ni) have become very important as copper alloys. They have the highest corrosion resistance of all copper alloys and find application as heat-exchanger tubing. Resistance to seawater is particularly outstanding. Cu-Ni-Sn spinodal strengthened alloys offer higher strength than the cupronickels along with excellent corrosion resistance. These alloys demonstrate very low weight loss in sulfide-containing environments and negligible weight loss in seawater.

The Copper Development Association has excellent references on copper and its alloys at <http://www.copper.org>.

**Lead and Alloys** Chemical leads of 99.9 percent purity are used primarily in the chemical industry in environments that form thin, insoluble, and self-repairable protective films, e.g., salts such as sulfates, carbonates, or phosphates. More soluble films such as nitrates, acetates, or chlorides offer little protection. Alloys of antimony, tin, and arsenic offer limited improvement in mechanical properties, but the usefulness of lead is limited primarily because of its poor structural qualities. It has a low melting point and tensile stress as low as 1 MPa (145 lbf/in<sup>2</sup>).

For information on lead and its uses, contact Lead Development Association International at <http://www.ldaint.org>.

**Titanium** Titanium has become increasingly important as a construction material. It is strong and of medium weight. Corrosion resistance is very superior in oxidizing and mild reducing media (Ti-Pd alloys Grade 7 and 11 have superior resistance in reducing environments, as does the Ti-Mo-Ni alloy Grade 12). Titanium alloys with lower amounts of Pd and Ru have been developed to reduce the cost (Grades 16 and 26). Titanium is usually not bothered by impingement attack, crevice corrosion, or pitting attack in seawater. Its general resistance to seawater is excellent. Titanium is resistant to nitric acid at all concentrations except with red fuming nitric. The metal also resists ferric chloride, cupric chloride, and other hot chloride solutions. However, there are a number of disadvantages to titanium which have limited its use. Titanium is not easy to form, it has a high springback and tends to gall, and welding must be carried out in an inert atmosphere.

For complete information on titanium, its properties and uses, contact the International Titanium Association at <http://www.ita.org>.

**Zirconium** Zirconium was originally developed as a construction material for atomic reactors. Reactor-grade zirconium contains very

little hafnium, which would alter zirconium's neutron-absorbing properties. Commercial-grade zirconium, for chemical-process applications, however, contains 2.5 percent maximum hafnium. Zirconium resembles titanium from a fabrication standpoint. All welding must be done under an inert atmosphere. Zirconium has excellent resistance to reducing environments. Oxidizing agents frequently cause accelerated attack. It resists all chlorides except ferric and cupric. Zirconium alloys should *not* be used in concentrations of sulfuric acid above about 70 percent. There are a number of alloys of titanium and zirconium, with mechanical properties superior to those of the pure metals.

**Tantalum** The physical properties of tantalum are similar to those of mild steel except that tantalum has a higher melting point. Tantalum is ductile and malleable and can be worked into intricate forms. It can be welded by using inert-gas-shielded techniques. The metal is practically inert to many oxidizing and reducing acids (except fuming sulfuric). It is attacked by hot alkalis and hydrofluoric acid. Its cost generally limits use to heating coils, bayonet heaters, coolers, and condensers operating under severe conditions. When economically justified, larger items of equipment (reactors, tanks, etc.) may be fabricated with tantalum liners, either loose (with proper anchoring) or explosion-bonded-clad. Since tantalum linings are usually very thin, very careful attention to design and fabrication details is required.

## CAST MATERIALS

**Cast Irons** Generally, cast iron is not a particularly strong or tough structural material, although it is one of the most economical and is widely used industrially.

**Gray cast iron**, low in cost and easy to cast into intricate shapes, contains carbon, silicon, manganese, and iron. Carbon (1.7 to 4.5 percent) is present as combined carbon and graphite; combined carbon is dispersed in the matrix as iron carbide (cementite), while free graphite occurs as thin flakes dispersed throughout the body of the metal. Various strengths of gray iron are produced by varying the size, amount, and distribution of graphite. Gray iron has outstanding damping properties, i.e., ability to absorb vibration, as well as wear resistance. However, gray iron is brittle, with poor resistance to impact and shock. Machinability is excellent. With some important exceptions, gray-iron castings generally have corrosion resistance similar to that of carbon steel. They do resist atmospheric corrosion as well as attack by natural or neutral waters and neutral soils. However, dilute acids and acid-salt solutions will attack this material. Gray iron is resistant to concentrated acids (nitric, sulfuric, phosphoric) as well as to some alkaline and caustic solutions. Caustic fusion pots are usually made from gray cast iron with low silicon content; cast-iron valves, pumps, and piping are common in sulfuric acid plants.

**White cast iron** is brittle and difficult to machine. It is made by controlling the composition and rate of solidification of the molten iron so that all the carbon is present in the combined form. Very abrasion- and wear-resistant, white cast iron is used as liners and for grinding balls, dies, and pump impellers.

**Malleable iron** is made from white cast iron. It is cast iron with free carbon as dispersed nodules. This arrangement produces a tough, relatively ductile material. Total carbon is about 2.5 percent. Two types are produced: standard and pearlitic (combined carbon plus nodules). Standard malleable iron is easily machined; pearlitic, less so. Both types will withstand bending and cold working without cracking. Large welded areas are not recommended with fusion welding because welds are brittle. Corrosion resistance is about the same as for gray cast iron.

**Ductile cast iron** includes a group of materials with good strength, toughness, wear resistance, and machinability. This type of cast iron contains combined carbon and dispersed nodules of carbon. Composition is about the same as that of gray iron, with more carbon (3.7 percent) than malleable iron. The spheroidal graphite reduces the notch effect produced by graphite flakes, making the material more ductile. There are a number of grades of ductile iron; some have maximum toughness and machinability, others have maximum resistance to oxidation. Generally, corrosion resistance is similar to that of gray iron. But ductile iron can be used at higher temperatures—up to 590°C (1100°F) and sometimes even higher.

**Alloy Cast Irons** Cast iron is not usually considered corrosion-resistant, but this condition can be improved by the use of various cast-iron alloys. A number of such materials are commercially available.

**High-silicon cast irons** have excellent corrosion resistance. Silicon content is 13 to 16 percent. This material is known as Durion. Adding 4 percent Cr yields a product called Durichlor, which has improved resistance in the presence of oxidizing agents. These alloys are not readily machined or welded. Silicon irons are very resistant to oxidizing and reducing environments, and resistance depends on the formation of a passive film. These irons are widely used in sulfuric acid service, since they are unaffected by sulfuric acid at all strengths, even up to the boiling point. Because they are very hard, silicon irons are good for combined corrosion-erosion service.

Another group of cast-iron alloys is called **Ni-Resist**. These materials are related to gray cast iron in that they have high carbon contents (3 percent), with fine graphite flakes distributed throughout the structure. Nickel contents range from 13.5 to 36 percent, and some have 6.5 percent Cu. Generally, nickel-containing cast irons have superior toughness and impact resistance compared with gray irons. The nickel-alloy castings can be welded and machined. Corrosion resistance of nickel-containing cast-iron alloys is superior to that of cast irons but less than that of pure nickel. There is little attack from neutral or alkaline solutions. Oxidizing acids such as nitric are highly detrimental. Cold, concentrated sulfuric acid can be handled. Ni-Resist has excellent heat resistance, with some grades serviceable up to 800°C (1500°F). Also, a ductile variety is available as well as a hard variety (Ni-Hard).

**Cast stainless alloys** are widely used in pumps, valves, and fittings. These casting alloys are designated under the ACI system. All corrosion-resistant alloys have the letter C plus a second letter (A to N) denoting increasing nickel content. Numerals indicate maximum carbon. While a rough comparison can be made between ACI and AISI types, compositions are not identical and analyses cannot be used interchangeably. Foundry techniques require a rebalancing of the wrought chemical compositions. However, corrosion resistance is not greatly affected by these composition changes. Typical members of this group are CF8, similar to type 304 stainless, and CF8M, similar to type CD3MWCuN, which represent the 25 Cr duplex stainless grades and have improved resistance to nitric, sulfuric, and phosphoric acids. Other duplex grades are CD3MN and CE3MN.

In addition to the C grades, there is a series of heat-resistant grades of ACI cast alloys, identified similarly to the corrosion-resistant grades, except that the first letter is H rather than C. Mention should also be made of precipitation-hardening (PH) stainless steels, which can be hardened by heat treatments at moderate temperatures. Very strong and hard at high temperatures, these steels have but moderate corrosion resistance. A typical PH steel, CB7Cu-1, containing 17 percent Cr, 7 percent Ni, and 1.1 percent Al, has high strength, good fatigue properties, and good resistance to wear and cavitation corrosion. A large number of these steels with varying compositions are commercially available. Essentially, they contain chromium and nickel with added alloying agents such as copper, aluminum, beryllium, molybdenum, nitrogen, and phosphorus.

**Medium Alloys** The group of (mostly) proprietary alloys with somewhat better corrosion resistance than stainless steels is called medium alloys. A popular member of this group is the **20 alloy**, made by a number of companies under various trade names. Durimet 20 is a well-known cast version, containing 0.07 percent C, 29 percent Ni, 20 percent Cr, 2 percent Mo, and 3 percent Cu. The ACI designation of this alloy is CN7M. Worthite is another proprietary 20 alloy with about 24 percent Ni and 20 percent Cr. The 20 alloy was originally developed to fill the need for a material with sulfuric acid resistance superior to that of the stainless steels. Also included are the 6Mo alloys such as CK3MCuN, similar to alloy 254SMO, and CN3MN, similar to alloy AL6XN.

Other members of the medium-alloy group do not have ACI designations but are listed in ASTM specifications (refer to ASTM A 494) such as **Incoloy 825 and Hastelloy G-3 and G-30**. Several nickel-based alloys that are normally only wrought have cast equivalents but are not listed in any specifications. Hastelloy G-3 contains 44 percent

Ni, 22 percent Cr, 6.5 percent Mo, and 0.05 percent C maximum while alloy G-30 has 30 percent Cr. These alloys have extensive applications in sulfuric acid systems. Because of their increased nickel and molybdenum contents they are more tolerant of chloride-ion contamination than are standard stainless steels. The nickel content decreases the risk of stress-corrosion cracking; molybdenum improves resistance to crevice corrosion and pitting. **Inconel 600** (80 percent Ni, 16 percent Cr, and 7 percent Fe) should also be mentioned as an intermediate alloy. It contains no molybdenum. The corrosion-resistant grade is recommended for reducing-oxidizing environments, particularly at high temperatures. When heated in air, this alloy resists oxidation up to 1100°C (2000°F). The alloy is outstanding in resisting corrosion by gases when these gases are essentially sulfur-free. The alloy is also used with a number of alkalies.

**High Alloys** The materials called high alloys all contain relatively large percentages of nickel. **N-12MV** contains 61 percent Ni and 28 percent Mo while **N7-M** has 63 percent Ni and 32 percent Mo. Control of carbon and silicon is better with **N7-M** and is important to receiving quality castings. Work hardening presents some fabrication difficulties, and machining is somewhat more difficult than for type 316 stainless. Conventional welding methods can be used. The alloy has unusually high resistance to all concentrations of hydrochloric acid at all temperatures in the absence of oxidizing agents. Sulfuric acid attack is low for all concentrations at 65°C (150°F), but the rate goes up with temperature. Oxidizing acids and salts rapidly corrode these Ni-Mo cast materials, but alkalies and alkaline solutions cause little damage.

**Ni-Cr-Mo** castings are covered by **CW-12MW**, which is a nickel-based alloy containing chromium (16 percent), molybdenum (16 percent), and tungsten (3 percent) as major alloying elements. This alloy is a cast modification of Hastelloy alloy C. This alloy is resistant to strong oxidizing chloride solutions, such as wet chlorine and hypochlorite solutions. It is one of the very few alloys which are totally resistant to seawater. **CW-6M** is a similar alloy with improved carbon control. Two improved alloys in this family are **CW-2M** and **CX-2MW**. The lower residuals in **CW-2M** provide for a material with much better thermal stability while the higher chromium of **CX-2MW** provides for better general corrosion resistance than the older grades.

**Casting Specifications of Interest** Refer to these specifications for the chemical analyses and properties of the various alloys:

1. ASTM A 217/A 217M-04 Standard Specification for Steel Castings, Martensitic Stainless and Alloy, for Pressure-Containing Parts, Suitable for High-Temperature Service (contains CA15)
2. ASTM A 297/A 297M-97(2003) Standard Specification for Steel Castings, Iron-Chromium and Iron-Chromium-Nickel, Heat Resistant, for General Application (contains most of the H grade, e.g., HP, castings)
3. ASTM A 351/A 351M-05 Standard Specification for Castings, Austenitic, Austenitic-Ferritic (Duplex), for Pressure-Containing Parts (contains most of the stainless grades, mostly corrosion, but some high-temperature)
4. ASTM A 494/A 494M-04 Standard Specification for Castings, Nickel and Nickel Alloy (contains many of the corrosion nickel alloy castings)
5. ASTM A 743/A 743M-03 Standard Specification for Castings, Iron-Chromium, Iron-Chromium-Nickel, Corrosion Resistant, for General Application (contains many of the corrosion grades)
6. ASTM A 744/A 744M-00(2004) Standard Specification for Castings, Iron-Chromium-Nickel, Corrosion Resistant, for Severe Service (contains some of the austenitic corrosion grades)
7. ASTM A 747/A 747M-04 Standard Specification for Steel Castings, Stainless, Precipitation Hardening (contains CB7Cu-1 and -2)
8. ASTM A 890/A 890M-99(2003) Standard Specification for Castings, Iron-Chromium-Nickel-Molybdenum Corrosion-Resistant, Duplex (Austenitic/Ferritic) for General Application (contains the major duplex grades)
9. ASTM A 990-05 Standard Specification for Castings, Iron-Nickel-Chromium and Nickel Alloys, Specially Controlled for Pressure Retaining Parts for Corrosive Service [currently contains CW-2M (C-4C) and two others].

**INORGANIC NONMETALLICS**

**Glass and Glassed Steel** Glass is an inorganic product of fusion which is cooled to a rigid condition without crystallizing. With unique properties compared with metals, these materials require special considerations in their design and use.

Glass has excellent resistance to all acids except hydrofluoric and hot, concentrated H<sub>3</sub>PO<sub>4</sub>. It is also subject to attack by hot alkaline solutions. Glass is particularly suitable for piping when transparency is desirable.

The chief drawback of glass is its brittleness, and it is also subject to damage by thermal shock. However, glass armored with epoxy-polyester fiberglass can readily be protected against breakage. On the other hand, glassed steel combines the corrosion resistance of glass with the working strength of steel. Accordingly, **glass linings** are resistant to all concentrations of hydrochloric acid to 120°C (250°F), to dilute concentrations of sulfuric to the boiling point, to concentrated sulfuric to 230°C (450°F), and to all concentrations of nitric acid to the boiling point. Acid-resistant glass with improved alkali resistance (up to 12 pH) is available.

A nucleated crystalline ceramic-metal composite form of glass has superior mechanical properties compared with conventional

glassed steel. Controlled high-temperature firings chemically and physically bond the ceramic to steel, nickel-based alloys, and refractory metals. These materials resist corrosive hydrogen chloride gas, chlorine, or sulfur dioxide at 650°C (1200°F). They resist all acids except HF up to 180°C (350°F). Their impact strength is 18 times that of safety glass; abrasion resistance is superior to that of porcelain enamel. They have 3 to 4 times the thermal-shock resistance of glassed steel.

**Porcelain and Stoneware** Porcelain and stoneware materials are about as resistant to acids and chemicals as glass, but with greater strength. This is offset by a greater potential for thermal shock. **Porcelain enamels** are used to coat steel, but the enamel has slightly inferior chemical resistance. Some refractory coatings, capable of taking very high temperatures, are also available.

**Brick Construction** Brick-lined construction can be used for many severely corrosive conditions under which high alloys would fail. Brick linings can be installed over metal, concrete, and fiberglass structures. Acid-resistant bricks are made from carbon, red shale, or acid-resistant refractory materials. Red-shale brick is not used above 175°C (350°F) because of spalling. Acid-resistant refractories can be used up to 870°C (1600°F). See Table 25-10.

 †Typical room-temperature properties of solution-annealed plates.  
 ‡To convert MPa to lbf/in<sup>2</sup>, multiply by 145.04.

A number of **cement** materials are used with brick. Standard are polymer resin, silicate, and sulfur-based materials. The most widely used resins are furane, vinyl ester, phenolic, polyester, and epoxies. Carbon-filled furanes and phenolics are good against nonoxidizing acids, salts, and solvents. Silicates and silica-filled resins should not be used in hydrofluoric or fluorosilicic acid applications. Sulfur-based cements are limited to 93°C (200°F), while resins can be used to about 180°C (350°F). Silicate-based cements are available for service temperatures up to 1000°C (1830°F).

Brick porosity, which can be as high as 20 percent, necessitates an intermediate lining of lead, asphalt, rubber, or plastic. This membrane functions as the primary barrier to protect the substrate from corrosion damage. The brick lining provides thermal and mechanical protection for the membrane. The membrane system also allows for the differential thermal expansion between the brick lining and supporting substrate. The design of brick linings exposed to higher operating pressure should take into account chemical expansion in addition to thermal expansion.

**Cement and Concrete** Concrete is an aggregate of inert reinforcing particles in an amorphous matrix of hardened cement paste. Concrete made of portland cement has limited resistance to acids and bases and will fail mechanically following absorption of crystal-forming solutions such as brines and various organics. Concretes made of corrosion-resistant cements (such as calcium aluminate) or polymer resins can be selected for specific chemical exposures.

**Soil** Clay is the primary construction material for settling basins and waste treatment evaporation ponds. Since there is no single type of clay even within a given geographic area, the shrinkage, porosity, absorption characteristics, and chemical resistance must be checked for each application. Geotextiles can be incorporated into basin and pond clay construction to improve the performance of the structure.

**ORGANIC NONMETALLICS**

Plastic polymers are materials made from organic compounds that have been joined to form long-chain, large-molecular-weight molecules that can be easily processed. There are two basic families of plastic polymers. Thermoplastics are a family of polymers that can be repeatedly heated, changed in shape, then cooled and solidified. Typical polymers within this family are polyolefins, polyvinyls, and the fluoropolymers. The second family of polymers is the thermosets. Unlike the thermoplastics, these materials crosslink during initial processing and cannot be reheated and reshaped. Upon reheating thermosets will not melt before they reach their decomposition temperature. Thermosets are typically more rigid than the thermoplastic polymers.

**Thermoplastics** Thermoplastics are used in a number of ways. They may be freestanding vessels, pipe, and other equipment; as linings in metallic vessels or as dual laminates in combination with thermoset

plastics. The processing of the thermoplastic raw materials has a great degree of influence on the final properties of the thermoplastic part. Processing techniques include extrusion, injection molding, compression molding, blow molding, rotational molding, and powder coating. Thermoplastics can be welded using various techniques. For critical applications it is highly recommended that welders be certified by independent, impartial organizations such as the German Welding Society (DVS) or a similar qualified organization. DVS certification is available in North America for the polymers and welding techniques covered within its guidelines. Visual inspection criteria for thermoplastic welds are available from the American Welding Society (AWS), DVS, and American Society of Mechanical Engineers Bio-processing standard (ASME- BPE). See Table 25-18 for typical thermoplastic properties.

The use of plastic polymers is limited to relatively moderate temperatures and pressures; 450°F (230°C) is considered high for polymers. They are also less resistant to mechanical abuse and have high expansion, low strength (thermoplastics), and only fair resistance to solvents. Plastic polymers are lightweight, are good thermal and electrical insulators, and are easy to fabricate and install. The chemical resistance of the thermoplastics is one of the major attributes of these materials. Virtually all chemical resistance tables and purity data are derived from the screen tests that were designed and for short-term environmental damage. Some long-term environmental data are available in the DVS guidelines. Care must be exercised when using these data as the test results are for individual chemicals and not typically mixtures of chemicals.

**Polytetrafluoroethylene (Teflon) (PTFE)** is the most corrosion-resistant thermoplastic polymer. This polymer is resistant to practically every known chemical or solvent combination and has the highest useful temperature of commercially available polymers. It retains its properties up to 500°F (260°C). Because of its exceedingly high molecular weight PTFE is processed by sintering. The PTFE resin is compressed into shapes under high pressure at room temperature and then heated to 700°F (371°C) to complete the sintering process.

**Fluorinated ethylene propylene (Teflon) (FEP)** is a fully fluorinated plastic. This polymer was developed to have a combination of unique properties. It combines the desirable properties of PTFE with advantageous melt processing properties.

**Perfluoroalkoxy (Teflon) (PFA)** was introduced in 1972 and is a fully fluorinated polymer that is melt-processible with better melt flow and molding properties than the FEP. The PFA has excellent resistance to chemicals. It can withstand acids as well as caustic materials. PFA has better mechanical properties than FEP above 300°F (149°C) and can be used up to 500°F (260°C) for some applications. The low physical strength and high cost of this polymer limit use for some applications.

**Polyvinylidene fluoride (Kynar) (PVDF)** is probably the most widely used fluorinated polymer for chemical applications. It can be melt-processed using virtually all the melt-processible procedures. PVDF components such as pipe fittings, tubing, sheet, shapes, and

\*Single values are maximum unless otherwise noted.

†Typical room-temperature properties.

‡To convert MPa to lbf/in<sup>2</sup>, multiply by 145.04.

§Single values are minima. Those alloys with N UNS numbers are nickel and R numbers are cobalt alloys.

other configurations are commercially available. PVDF has a use range from -40 to 302°F (150°C). PVDF has a high tensile strength, flex modulus, and heat deflection temperature. It is easily welded, resists permeation, and offers a high-purity smooth polymer surface. This is the polymer of choice for high-purity applications such as semiconductor, bioprocessing, and pharmaceutical industries.

**Ethylene chlorotrifluoroethylene** (Halar) (ECTFE) has excellent chemical resistance to most chemicals including caustic. ECTFE can be used from -105°F (-76°C) to 302°F (150°C). To obtain good extrusion characteristics, this polymer is usually compounded with a small amount of extrusion aid.

**Ethylene trifluoroethylene** (Tefzel) (ETFE) has good mechanical properties from cryogenic levels to 350°F (177°C). It has an upper continuous working temperature limit of 300°F (149°C).

**Polyethylene** (PE) is one of the lowest-cost polymers. There are various types of polyethylene denoted by their molecular weight. This ranges from low-density polyethylene (LDPE) through ultrahigh-molecular-weight (UHMW) polyethylene. Physical properties, processability, and other characteristics of the polyethylene vary greatly with the molecular weight.

**Polypropylene** (PP) is a crystalline polymer suitable for low-stress applications up to 225°F (105°C). For piping applications this polymer is not recommended above 212°F (100°C). Polypropylene is shielded, pigmented, or stabilized to protect it from uv light. Polypropylene is often a combination of polyethylene and polypropylene which enhances the ductility of the polymer.

**Polyvinyl chloride** (PVC) has excellent resistance to weak acids and alkaline materials. PVC is commonly utilized for applications that do not require high-temperature resistance or a high-purity resin. Chlorinated PVC (CPVC or PVC-C) represents more than 80 percent of all the PVC used in North America. PVC contains 56.8 percent chlorine by weight in contrast to about 67 percent for CPVC. Both PVC and CPVC are compounded with ingredients such as heat stabilizers, lubricants, fillers, plasticizers, pigments, and processing aids. The actual amount of polymer may range from 93 to 98 percent. The remaining 2 to 7 percent is filler, pigment, stabilizer, lubricant, and plasticizer.

Other commercial thermoplastics include **acrylonitrile butadiene styrene** (ABS), **cellulose acetate butyrate** (CAB), **polycarbonate** (PC), **nylon** (PA), and **acetals**. These resins are frequently used in consumer applications.

**Thermosets\*** There are several generic types of thermosetting resins used for the manufacture of fiberglass-reinforced plastic (FRP composites) equipment. Unlike thermoplastic polymers, thermosetting polymers are hardened by an irreversible crosslinking cure and are almost exclusively used with fiber reinforcement such as glass or carbon fibers in structural applications. It is important to note that because thermoset resins are used with fiber reinforcements, the properties of the resultant laminate are dependent upon the resin and the type, amount, and orientation of reinforcement fibers. To reduce the number of generally used constructions, ASTM and ASME RTP-1 define several standard corrosion-resistant laminate constructions suitable for most equipment. In addition to new construction, thermoset composites are providing practical solutions to the engineer faced with the challenges of restoring structural integrity, increasing load-bearing capabilities, and/or enhancing the strength and stiffness of aging structures. See Table 25-19 for typical thermoset fiber reinforced laminate properties.

The advantages of composites are inherent in their construction. A variety of resin/fiber systems can yield possible solutions for many types of situations. Depending on the product and application, FRP products for civil and mechanical applications can deliver the following benefits:

- Part design (orientation of the fibers) can be optimized for specific loads.
- Reduced structure dead load can increase load ratings.
- Reduced maintenance costs due to resistance from salts and other corrosive agents.
- Engineered system packaging reduces field installation time.
- Faster installation due to lower weight.
- Enhanced durability and fatigue characteristics—FRP does not rust nor is it chloride susceptible.
- Myriad FRP products are available for either the repair or the outright replacement of existing structures. In addition to chemical-process pipes and tanks, FRP composite products include structural shapes, bridge systems, grating, handrail ladders, etc.

\*Note: Thermosets are also used in non-fiber-reinforced applications such as gel coats and cast polymer.

<sup>a</sup>Polyester thermosets can be formulated to meet a wide range of flame, smoke, and toxicity specifications.

**Epoxy (Amine-Cured)** Bisphenol A-based epoxy resins used for composite fabrication are commonly cured with multifunctional primary amines. For optimum chemical resistance these generally require a heat cure or postcure. The cured resin has good chemical resistance, particularly to basic environments, and can have good temperature resistance.

**Epoxy (Anhydride-Cured)** Epoxy resins may be crosslinked with various anhydrides by using a tertiary amine accelerator and heat. These cured polymers generally have good chemical resistance especially to acids.

**Epoxy Vinyl Ester** Vinyl ester resins are typified by a highly aromatic Bisphenol-A structure and exhibit a broad range of chemical resistance, particularly to caustic solutions, and are the most resilient of the corrosion-resistant resins, generally resulting in the toughest laminate. Brominated versions have about the same corrosion resistance as other Bisphenol-A vinyl esters plus they offer a degree of fire retardancy. The novolac vinyl ester resins exhibit high-temperature resistance and a broad range of chemical resistance, particularly to solvents, oxidizing media, and strong acids.

**Bisphenol-A Fumarate Polyester** These resins exhibit a broad range of chemical resistance, particularly to caustic solutions. Brominated versions have about the same corrosion resistance as other Bisphenol-A vinyl esters plus they offer a degree of fire retardancy.

**Chlorendic Acid Polyester** These resins have excellent resistance to acids, good resistance to oxidizing acid media and high-temperature resistance, and moderate fire resistance.

**Furan** Furan resins are thermosetting polymers derived from furfuryl alcohol and Furfural. The cure must be carefully controlled to avoid the formation of blisters and delaminations. To obtain optimum strength and corrosion resistance, furan composites must undergo a postcure schedule at carefully selected temperatures depending upon the laminate thickness. Equipment made with furan resins exhibits excellent resistance to solvents and combinations of acids and solvents. These resins are not for use in strong oxidizing environments.

**Isophthalic/Terephthalic Acid Polyester** Typically, isophthalic acid is reacted in a two-stage process with glycols such as propylene or neopentyl glycol and then with maleic anhydride. The crosslinked, fully cured isophthalic-based composites exhibit good weathering resistance and good corrosion resistance to acid media.

**Dual-Laminate Construction and Linings** The availability of some of the thermoplastic resins in sheet form with a bondable surface allows them to be utilized in a fashion similar to metal cladding. The sheets can be bonded in place and welded to form a barrier surface. When they are used in conjunction with thermoset resin technology for the fabrication of vessels, the procedure is referred to as *dual-laminate*. This fabrication technique extends the chemical resistance of the thermoset resin and the structural strength of the thermoplastic, providing a strong vessel that is highly chemically resistant internally and externally yet lightweight and easily fabricated. Standards for the fabrication of dual-laminate structures can be found in the ASME RTP-1 standard. See Table 25-20 for dual-laminate construction and lining properties.

**Rubber and Elastomers** Rubber and elastomers are widely used as lining materials. To meet the demands of the chemical industry, rubber processors are continually improving their products. A number of synthetic rubbers have been developed, and while none has all the properties of natural rubber, they are superior in one or more ways. The isoprene and polybutadiene synthetic rubbers are duplicates of natural.

The ability to bond natural rubber to itself and to steel makes it ideal for lining tanks. Many of the synthetic elastomers, while more chemically resistant than natural rubber, have very poor bonding characteristics and hence are not well suited for lining tanks.

**Natural rubber** is resistant to dilute mineral acids, alkalis, and salts, but oxidizing media, oils, and most organic solvents will attack it. **Hard rubber** is made by adding 25 percent or more of sulfur to natural or synthetic rubber and, as such, is both hard and strong. **Chloroprene** or **neoprene rubber** is resistant to attack by ozone, sunlight, oils, gasoline, and aromatic or halogenated solvents but is

easily permeated by water, thus limiting its use as a tank lining. **Styrene rubber** has chemical resistance similar to that of natural. **Nitrile rubber** is known for resistance to oils and solvents. **Butyl rubber's** resistance to dilute mineral acids and alkalis is exceptional; resistance to concentrated acids, except nitric and sulfuric, is good. **Silicone rubbers**, also known as polysiloxanes, have outstanding resistance to high and low temperatures as well as against aliphatic solvents, oils, and greases. **Chlorosulfonated polyethylene**, known as **Hypalon**, has outstanding resistance to ozone and oxidizing agents except fuming nitric and sulfuric acids. Oil resistance is good. **Fluoroelastomers (Viton A, Kel-F, Kalrez)** combine excellent chemical and temperature resistance. **Polyvinyl chloride elastomer (Koro seal)** was developed to overcome some of the limitations of natural and synthetic rubbers. It has excellent resistance to mineral acids and petroleum oils.

The **cis-polybutadiene**, **cis-polyisoprene**, and **ethylene-propylene** rubbers are close duplicates of natural rubber. The newer ethylene-propylene rubbers (EPR) have excellent resistance to heat and oxidation.

**Asphalt** Asphalt is used as a flexible protective coating, as a brick-lining membrane, and as a chemical-resisting floor covering and road surface. Resistant to acids and bases, asphalt is soluble in organic solvents such as ketones, most chlorinated hydrocarbons, and aromatic hydrocarbons.

**Carbon and Graphite** The chemical resistance of impervious carbon and graphite depends somewhat on the type of resin impregnated used to make the material impervious. Generally, impervious graphite is completely inert to all but the most severe oxidizing conditions. This property, combined with excellent heat transfer, has made impervious carbon and graphite very popular in heat exchangers, as brick lining, and in pipe and pumps. One limitation of these materials is low tensile strength. Threshold oxidation temperatures are 350°C (660°F) for carbon and 400°C (750°F) for graphite.

Several types of resin impregnates are employed in manufacturing impervious graphite. The standard impregnant is a phenolic resin suitable for service in most acids, salt solutions, and organic compounds. A modified phenolic impregnant is recommended for service in alkalis and oxidizing chemicals. Furan and epoxy thermosetting resins are also used to fill structural voids. The chemical resistance of the impervious graphite is controlled by the resin used. However, no type of impervious graphite is recommended for use in over 60 percent hydrofluoric, over 20 percent nitric, and over 96 percent sulfuric acids and in 100 percent bromine, fluorine, or iodine.

**Wood** While fairly inert chemically, wood is readily dehydrated by concentrated solutions and hence shrinks badly when subjected to the action of such solutions. It is also slowly hydrolyzed by acids and alkalis, especially when hot. In tank construction, if sufficient shrinkage once takes place to allow crystals to form between the staves, it becomes very difficult to make the tank tight again.

A number of manufacturers offer wood impregnated to resist acids or alkalis or the effects of high temperatures.

Wood, one of people's oldest materials, remains an important (and too often, overlooked) *corrosion-resistant* material of construction in the chemical-process industry. Wood tanks and wood piping have long met engineers' requirements for dependable service and excellent performance in industrial applications. A very thorough and detailed treatise can be found in a three-part publication, by Oliver W. Siebert, "Wood—Nature's High-Performance Material," NACE, *Materials Performance*, vol. 31, nos. 1-3, January through March 1992.\*

Types of wood and their chemical resistance and physical characteristics are reviewed, including examples showing the manufacture of typical tank and pipe construction. In-service case histories are included. While this coverage takes you from the "Forest" to the plants making acetic acid, that is beyond the need for most users; it is hoped that the reader becomes aware that this product family is the *only* MOC for several CPI applications and is a *competitive* choice over some quite exotic materials, e.g., titanium, in others.

**HIGH- AND LOW-TEMPERATURE MATERIALS**

**LOW-TEMPERATURE METALS**

The low-temperature properties of metals have created some unusual problems in fabricating cryogenic equipment.

Most metals lose their ductility and impact strength at low temperatures, although in many cases yield and tensile strengths increase as the temperature goes down.

Materials selection for low-temperature service is a specialized area. In general, it is necessary to select materials and fabrication methods which will provide adequate toughness at all operating conditions. It is frequently necessary to specify Charpy V-notch (or other appropriate) qualification tests to demonstrate adequate toughness of carbon and low-alloy steels at minimum operating temperatures.

**Stainless Steels** Chromium-nickel steels are suitable for service at temperatures as low as -250°C (-425°F). Type 304 is the most pop-

ular. The original cost of stainless steel may be higher than that of another metal, but ease of fabrication (no heat treatment) and welding, combined with high strength, offsets the higher initial cost. Sensitization or formation of chromium carbides can occur in several stainless steels during welding, and this will affect impact strength. However, tests have shown that impact properties of types 304 and 304L are not greatly affected by sensitization but that the properties of 302 are impaired at -185°C (-300°F).

**Nickel Steel** Low-carbon 9 percent nickel steel is a ferritic alloy developed for use in cryogenic equipment operating as low as -195°C (-320°F). ASTM specifications A 300 and A 353 cover low-carbon 9 percent nickel steel (A 300 is the basic specification for low-temperature ferritic steels). Refinements in welding and (ASME code-approved) elimination of postweld thermal treatments make 9 percent steel competitive with many low-cost materials used at low temperatures.

TABLE 25-21 Copper Alloys

**Nickel Alloys** Alloy C-4 (16 Cr, 16 Mo, Balance Ni) and alloy C-276 (16 Cr, 16 Mo, 3.5 W, 5 Fe, balance Ni) have been used for closure seals on cryogenic gas cylinders because the alloys retain all their ductility down to -327°C (-557°F). The impact strength at liquid nitrogen temperatures is the same as that at room temperature.

**Aluminum** Aluminum alloys have an unusual ability to maintain strength and shock resistance at temperatures as low as -250°C (-425°F). Good corrosion resistance and relatively low cost make these alloys very popular for low-temperature equipment. For most welded construction the 5000-series aluminum alloys are widely used. These are the aluminum-magnesium and aluminum-magnesium-manganese materials.

**Copper and Alloys** With few exceptions the tensile strength of copper and its alloys increases quite markedly as the temperature goes

down. However, copper's low structural strength becomes a problem when constructing large-scale equipment. Therefore, alloy must be used. One of the most successful for low temperatures is silicon bronze, which can be used to -195°C (-320°F) with safety.

**HIGH-TEMPERATURE MATERIALS\***

**Metals** Successful applications of metals in high-temperature process service depend on an appreciation of certain engineering factors. Among the most important properties are creep, rupture,

\*An excellent reference book for the high-temperature corrosion resistance of materials of construction is George Y. Lai, *High-Temperature Corrosion of Engineering Alloys*, ASM International, Metals Park, Ohio, 1990.

**FIG. 25-21** Effect of creep on metals for high-temperature use. °C = (°F - 32) × 5/9; to convert lbf/in<sup>2</sup> to MPa, multiply by 6.895 × 10<sup>-3</sup>. [Chem. Eng., 65, p. 140 (Dec. 15, 1958); modified 2005 using producer data.]

and short-time strengths (see Figs. 25-21 and 25-22). **Creep** relates initially applied stress to rate of plastic flow. **Stress rupture** is another important consideration at high temperatures since it relates stress and time to produce rupture. As the figures show, ferritic alloys are weaker than austenitic compositions, and in both groups molybdenum increases strength. Austenitic castings are much stronger than their wrought counterparts. And higher strengths are available in the nickel- and cobalt-based alloys. Other properties that become important at high temperatures include thermal conductivity,

**FIG. 25-22** Rupture properties of metals as a function of temperature. °C = (°F - 32) × 5/9; to convert lbf/in<sup>2</sup> to MPa, multiply by 6.895 × 10<sup>-3</sup>. [Chem. Eng., 65, p. 140 (Dec. 15, 1958); modified 2005 using producer data.]

thermal expansion, ductility at temperature, alloy composition, and stability.

Actually, in many cases strength and mechanical properties become of secondary importance in process applications, compared with resistance to the corrosive surroundings. All common heat-resistant alloys form oxides when exposed to hot oxidizing environments. Whether the alloy is resistant depends upon whether the oxide is stable and forms a protective film. Thus, mild steel is seldom used above 480°C (900°F) because of excessive scaling rates. Higher temperatures require chromium. Thus, type 502 steel, with 4 to 6 percent Cr, is acceptable to 620°C (1150°F). A 9 to 12 percent Cr steel will handle 730°C (1350°F). The well-known austenitic stainless steels have excellent oxidation resistance: up to 900°C (1650°F) for 18-8; however, their strength limits their use. Chromium is also important in nickel-based alloys as a very protective chromium-nickel spinel oxide forms at lower temperatures. At temperatures above 1000°C (1832°F) the addition of significant quantities of aluminum or silicon will enhance the oxidation resistance. There is a synergistic effect between silicon or aluminum in the formation of more resistant oxide layers.

Figure 25-23 shows the oxidation resistance of a variety of commercially significant alloys. The penetration shown is a combination of the uniform scaling that occurred during exposure and the internal penetration of oxide into the microstructure. This value of penetration is considered to be conservative but better from a prediction of life basis. The lower curve for alloy 214 shows the beneficial effect of aluminum in reducing oxidation at high temperatures; however, the use of this alloy is limited by its high temperature strength. These curves were generated using a program called ASSET that was developed by Shell Global solutions and is available for purchase. The curves are based on actual data that were generated and then used to calculate a parameter that allows extrapolation to different temperatures. The heavy line is from actual data while the thin line is extrapolated data.

Chromium is the most important material in imparting resistance to sulfidation (formation of sulfidic scales similar to oxide scales). The austenitic alloys are generally used because of their superior mechanical properties and fabrication qualities, despite the fact that nickel in the alloy tends to lessen resistance to sulfidation somewhat.

*Aluminum* and *silicon* also improve the resistance of alloys to oxidation as well as sulfidation. But use as an alloying agent is limited because the amount required interferes with the workability and

**FIG. 25-23** Penetration curves for oxidation in still air of several commercially significant high-temperature alloys.

NOTE: All physical values depend greatly on reinforcing. Values are for ambient temperatures.

\*Type of urethane used is one of three: (1) Type II, moisture-cured; (2) Type IV, two-package catalyst; or (3) Type V, two-package polyol. (Ref. ASTM C16.)

†Urethanes not shown because of great differences in physical properties, depending on formulations. Adhesion characteristics should be related by actual test data. Any system which shows concrete failure when tested for surfacing adhesion should be rated excellent with decreasing rating for systems showing failure in cohesion or adhesion below concrete failure.

‡Adhesion to concrete: primers generally are used under polyesters and urethanes to improve adhesion.

high-temperature strength properties. The formation of Ni<sub>3</sub>Al precipitates in a nickel alloy increases the strength but reduces the ductility. The development of high aluminum surface layers by spraying, dipping, and cementation is a feasible means of improving the corrosion resistance of low-alloy steels.

**Hydrogen Atmospheres** Austenitic stainless steels, by virtue of their structure and high chromium contents, are usually resistant to hydrogen atmospheres. Ferritic alloys are more susceptible to hydrogen embrittlement.

**TABLE 25-24 Chemical Resistance of Elastomers**

| Type of rubber                    | Features  |
|-----------------------------------|---|
| Butadiene styrene                 | General-purpose; poor resistance to hydrocarbons, oils, and oxidizing agents  |
| Butyl                             | General-purpose; relatively impermeable to air; poor resistance to hydrocarbons and oils  |
| Chloroprene                       | Good resistance to aliphatic solvents; poor resistance to aromatic hydrocarbons and many fuels  |
| Chlorosulfonated polyethylene     | Excellent resistance to oxidation, chemicals, and heat; poor resistance to aromatic oils and most fuels   |
| cis-Polybutadiene                 | General-purpose; poor resistance to hydrocarbons, oils, and oxidizing agents  |
| cis-Polyisoprene                  | General-purpose; poor resistance to hydrocarbons, oils, and oxidizing agents  |
| Ethylene propylene Fluorinated    | Excellent resistance to heat and oxidation  |
| Natural                           | Excellent resistance to high temperature, oxidizing acids, and oxidation; good resistance to fuels containing up to 30% aromatics   |
| Nitrile (butadiene acrylonitrile) | General-purpose; poor resistance to hydrocarbons, oils, and oxidizing agents  |
| Polysulfide                       | Excellent resistance to oils, but not resistant to strong oxidizing agents; resistance to oils proportional to acrylonitrile content  |
| Silicone                          | Good resistance to aromatic solvents; unusually high impermeability to gases; poor compression set and poor resistance to oxidizing acids   |
| Styrene                           | Excellent resistance over unusually wide temperature range [–100 to 260°C (–150 to 500°F)]; fair oil resistance; poor resistance to aromatic oils, fuels, high-pressure steam, and abrasion |
|                                   | Synonymous with butadiene-styrene   |

**Halogens (Hot, Dry Cl<sub>2</sub>, HCl)** Pure nickel and nickel alloys are useful with dry halogen gases. The presence of oxygen with Cl<sub>2</sub> or HCl gas will alter the choice of materials. But even with the best materials, corrosion rates are relatively high at high temperature. There are cases in which equipment for high-temperature halogenation has used platinum-clad nickel-based alloys. These materials have high initial cost but long life. Platinum and gold have excellent resistance to dry HCl even at 1100°C (2000°F).

**Refractories** Refractories are selected to accomplish four objectives:

1. Resist heat
2. Resist high-temperature chemical attack
3. Resist erosion by gas with fine particles
4. Resist abrasion by gas with large particles

Refractories are available in three general physical forms: solids in the form of brick and monolithic castable ceramics and as ceramic fibers.

The primary method of selection of the type of refractory to be used is by gas velocity:

- <7.5 m/s (25 ft/s): fibers
- 7.5–60 m/s (25–200 ft/s): monolithic castables
- >60 m/s (200 ft/s): brick

Within solids the choice is a tradeoff because, with brick, fine particles in the gas remove the mortar joints and, in the monolithic castables, while there are no joints, the refractory is less dense and less wear-resistant.

**Internal Insulation** The practice of insulating within the vessel (as opposed to applying insulating materials on the equipment exterior) is accomplished by the use of fiber blankets and lightweight aggregates in ceramic cements. Such construction frequently incorporates a thin, high-alloy shroud (with slip joints to allow for thermal expansion) to protect the ceramic from erosion. In many cases this design is more economical than externally insulated equipment because it allows use of less expensive lower-alloy structural materials.

**Refractory Brick** Nonmetallic refractory materials are widely used in high-temperature applications in which the service permits the appropriate type of construction. The more important classes are described in the following paragraphs.

Fireclays can be divided into plastic clays and hard flint clays; they may also be classified as to alumina content. **Firebricks** are usually made of a blended mixture of flint clays and plastic clays which is formed, after mixing with water, to the required shape. Some or all of

TABLE 25-25 Properties of Graphite and Silicon Carbide

|  | Graphite                        | Impervious graphite      | Impervious silicon carbide |

the flint clay may be replaced by highly burned or calcined clay, called *grog*. A large proportion of modern brick production is molded by the dry-press or power-press process, in which the forming is carried out under high pressure and with a low water content. Extruded and hand-molded bricks are still made in large quantities.

The dried bricks are burned in either periodic or tunnel kilns at temperatures ranging between 1,200 and 1,500°C (2,200 and 2,700°F). Tunnel kilns give continuous production and a uniform burning temperature.

Fireclay bricks are used in kilns, malleable-iron furnaces, incinerators, and many portions of metallurgical furnaces. They are resistant to spalling and stand up well under many slag conditions but are not generally suitable for use with high-lime slags or fluid-coal-ash slags or under severe load conditions.

**High-alumina bricks** are manufactured from raw materials rich in alumina, such as diaspore. They are graded into groups with 50, 60, 70, 80, and 90 percent alumina content. When well fired, these bricks contain a large amount of mullite and less of the glassy phase than is present in firebricks. Corundum is also present in many of these bricks. High-alumina bricks are generally used for unusually severe temperature or load conditions. They are employed extensively in lime kilns and rotary cement kilns, in the ports and regenerators of glass tanks, and for slag resistance in some metallurgical furnaces; their price is higher than that of firebrick.

**Silica bricks** are manufactured from crushed ganister rock containing about 97 to 98 percent silica. A bond consisting of 2 percent lime is used, and the bricks are fired in periodic kilns at temperatures of 1,500 to 1,540°C (2,700 to 2,800°F) for several days until a stable volume is obtained. They are especially valuable when good strength is required at high temperatures. Superduty silica bricks are finding some use in the steel industry. They have a lowered alumina content and often a lowered porosity.

Silica bricks are used extensively in coke ovens, the roofs and walls of open-hearth furnaces, and the roofs and sidewalls of glass tanks and

as linings of acid electric steel furnaces. Although silica brick is readily spalled (cracked by a temperature change) below red heat, it is very stable if the temperature is kept above this range and for this reason stands up well in regenerative furnaces. Any structure of silica brick should be heated up slowly to the working temperature; a large structure often requires 2 weeks or more.

**Magnesite bricks** are made from crushed magnesium oxide, which is produced by calcining raw magnesite rock to high temperatures. A rock containing several percent of iron oxide is preferable, as this permits the rock to be fired at a lower temperature than if pure materials were used. Magnesite bricks are generally fired at a comparatively high temperature in periodic or tunnel kilns. A large proportion of magnesite brick made in the United States uses raw material extracted from seawater.

Magnesite bricks are basic and are used whenever it is necessary to resist high-lime slags, as in the basic open-hearth steel furnace. They also find use in furnaces for the lead- and copper-refining industries. The highly pressed unburned bricks find extensive use as linings for cement kilns. Magnesite bricks are not so resistant to spalling as fireclay bricks.

**Chrome bricks** are manufactured in much the same way as magnesite bricks but are made from natural chromite ore. Commercial ores always contain magnesia and alumina. Unburned hydraulically pressed chrome bricks are also available.

Chrome bricks are very resistant to all types of slag. They are used as separators between acid and basic refractories, also in soaking pits and floors of forging furnaces. The unburned hydraulically pressed bricks now find extensive use in the walls of the open-hearth furnace. Chrome bricks are used in sulfite-recovery furnaces and to some extent in the refining of nonferrous metals. Basic bricks combining various properties of magnesite and chromite are now made in large quantities and have advantages over either material alone for some purposes.

The **insulating firebrick** is a class of brick that consists of a highly porous fire clay or kaolin. Such bricks are light in weight (about one-half to one-sixth of the weight of fireclay), low in thermal conductivity, and yet sufficiently resistant to temperature to be used successfully on the hot side of the furnace wall, thus permitting thin walls of low thermal conductivity and low heat content. The **low heat content** is particularly valuable in saving fuel and time on heating up, allows rapid changes in temperature to be made, and permits rapid cooling. These bricks are made in a variety of ways, such as mixing organic matter with the clay and later burning it out to form pores; or a bubble structure can be incorporated in the clay-water mixture which is later preserved in the fired brick. The insulating firebricks are classified into several groups according to the maximum use limit; the ranges are up to 870, 1,100, 1,260, 1,430, and above 1,540°C (1,600, 2,000, 2,300, 2,600, and above 2,800°F).

Insulating refractories are used mainly in the heat-treating industry for furnaces of the periodic type. They are also used extensively in stress-relieving furnaces, chemical-process furnaces, oil stills or heaters, and the combustion chambers of domestic-oil-burner furnaces. They usually have a life equal to that of the heavy brick that they replace. They are particularly suitable for constructing experimental or

laboratory furnaces because they can be cut or machined readily to any shape. They are not resistant to fluid slag.

There are a number of types of special brick obtainable from individual producers. **High-burned kaolin refractories** are particularly valuable under conditions of severe temperature and heavy load or severe spalling conditions, as in the case of high-temperature oil-fired boiler settings or piers under enameling furnaces. Another brick for the same uses is a high-fired brick of Missouri aluminous clay.

There are on the market a number of bricks made from **electrically fused materials**, such as fused mullite, fused alumina, and fused magnesite. These bricks, although high in cost, are particularly suitable for certain severe conditions.

Bricks of **silicon carbide**, either recrystallized or clay-bonded, have a high thermal conductivity and find use in muffle walls and as a slag-resisting material.

Other types of refractory that find use are forsterite, zirconia, and zircon. Acid-resisting bricks consisting of a dense body like stoneware are used for lining tanks and conduits in the chemical industry. Carbon blocks are used as linings for the crucibles of blast furnaces, very extensively in a number of countries and to a limited extent in the United States. Fusion-cast bricks of mullite or alumina are largely used to line glass tanks.

**Ceramic-Fiber Insulating Linings** Ceramic fibers are produced by melting the same alumina-silica china (kaolin) clay used in conventional insulating firebrick and blowing air to form glass fibers. The fibers, 50.8 to 101.6 mm (2 to 4 in) long by 3 µm in diameter, are interlaced into a mat blanket with no binders or chopped into shorter fibers and vacuum-formed into blocks, boards, and other shapes. Ceramic-fiber linings, available for the temperature range of 650 to 1,430°C (1,200 to 2,600°F), are more economical than brick in the 650 to 1,230°C (1,200 to 2,250°F) range. Savings come from reduced first costs, lower installation labor, 90 to 95 percent less weight, and a 25 percent reduction in fuel consumption.

Because of the larger surface area (compared with solid-ceramic refractories) the chemical resistance of fibers is relatively poor. Their acid resistance is good, but they have less alkali resistance than solid materials because of the absence of resistant aggregates. Also, because they have less bulk, fibers have lower gas-velocity resistance. Besides the advantage of lower weight, since they will not hold heat, fibers are more quickly cooled and present no thermal-shock structural problem.

**Castable Monolithic Refractories** Standard portland cement is made of calcium hydroxide. In exposures above 427°C (800°F) the hydroxyl ion is removed from portland (water removed); below 427°C (800°F), water is added. This cyclic exposure results in spalling. Castables are made of calcium aluminate (rather than portland); without the hydroxide they are not subject to that cyclic spalling failure.

Castable refractories are of three types:

1. *Standard.* 40 percent alumina for most applications at moderate temperatures.

2. *Intermediate purity.* 50 to 55 percent alumina. The anorthite (needle-structure) form is more resistant to the action of steam exposure.

3. *Very pure.* 70 to 80 percent alumina for high temperatures. Under reducing conditions the iron in the ceramic is controlling, as it acts as a catalyst and converts the CO to CO<sub>2</sub> plus carbon, which results in spalling. The choice among the three types of castables is generally made by economic considerations and the temperature of the application.

Compared with brick, castables are less dense, but this does not really mean that they are less serviceable, as their cements can hydrate and form gels which can fill the voids in castables. Extra-large voids do indicate less strength regardless of filled voids and dictate a lower allowable gas velocity. If of the same density as a given brick, a castable will result in less permeation.

Normally, castables are 25 percent cements and 75 percent aggregates. The aggregate is the more chemically resistant of the two components. The highest-strength materials have 30 percent cement, but too much cement results in too much shrinkage. The standard insulating refractory, 1:2:4 LHV castable, consists of 1 volume of cement, 2 volumes of expanded clay (Haydite), and 4 volumes of vermiculite.

Castables can be modified by a clay addition to keep the mass intact, thus allowing application by air-pressure gunning (gumite). Depending upon the size and geometry of the equipment, many castable linings must be reinforced; wire and expanded metal are commonly used.

acentric factor, **2-473 to 2-475**  
acetic acid:  
  Antoine vapor pressure, **13-14**  
  BIP data, **13-13**  
acetic-acid/water separation, **15-8**  
acetone:  
  absorption in water, **14-17**  
  Antoine vapor pressure, **13-14**  
  BIP data, **13-13**  
  residue curve, **13-90**  
  residue map, **13-79**  
  thermodynamic properties, **2-209 to 2-210**  
  VLE data, **13-7, 13-9**  
acetylene, saturated, thermodynamic properties, **2-186, 2-210**  
acid catalyzed isomerization, **7-15**  
acrylonitrile, **17-17**  
activated complex, **7-14**  
activation energy, **7-6**  
activation overpotential, **7-32**  
activity, **12-26, 12-28**  
actuator, **8-76 to 8-77, 8-84**  
A/D converter, **8-66**  
A/D integrating, **8-66**  
adaptive control, **8-26**  
adiabatic adsorption, breakthrough curves, **16-33 to 16-34**  
adiabatic saturation temperature, **12-5**  
adjusted propagation velocity, **16-46**  
adsorbed-solution theory, **16-15**  
adsorbents:  
  classification, **16-8**  
  physical properties, **16-10**  
adsorption:  
  equipment:  
    adsorber vessel, **16-61 to 16-63**  
    cycle control, **16-64**  
    design, **16-61**  
    hypersorption, **16-66**  
    PuraSiv HR vessel, **16-66**  
    regeneration, **16-63**  
  continuous countercurrent systems, **16-64**  
  cross-flow systems, **16-64**  
  pollutants, **22-37**  
  pressure-swing, **16-50**  
  process descriptors, **16-60**  
  process selection matrix, **16-60**  
  reaction rates, **7-19**  
  temperature swing, **16-49**  
  UOP nine-bed polybed PSA H2 unit, **16-65**  
adsorption and ion exchange:  
  adsorbents and ion exchangers, **16-8 to 16-9**  
  batch adsorption, **16-27 to 16-30**  
  chromatography, **16-38 to 16-48**  
  conservation equations, **16-17 to 16-18**  
  design concepts, **16-4 to 16-7**  
  equipment, **16-61 to 16-67**  
  fixed-bed transitions, **16-31 to 16-38**  
  process cycles, **16-49 to 16-60**  
  rate and dispersion factors, **16-18 to 16-25**  
  sorption equilibrium, **16-11 to 16-14**  
adsorption cycles:  
  energy application, **16-58**  
  hybrid recycle systems, **16-58**  
  steam regeneration, **16-58**  
adsorption equilibrium, **7-16**  
adsorption-desorption, rapid, **16-25**  
adsorption-rate controlling, reaction kinetics, **7-18**  
adsorptive bubble separation methods:  
  adsorption:  
    factors affecting, **20-31**  
    limiting equations, **20-31 to 20-33**  
    bubble fractionation, **20-34 to 20-35**  
  adsorptive bubble separation methods (*Cont.*):  
    definition and classification, **20-30 to 20-31**  
    foam-column theory:  
      breaking, **20-34**  
      coalescence, **20-34**  
      drainage and overflow, **20-34**  
      equations, **20-32 to 20-33**  
      operation, **20-33**  
  aerobic, biocatalysis, **7-18**  
  aerobic fermentation, **7-30**  
  aerodynamic diameter, **17-24**  
  affinity laws, **10-36**  
  agglomerated materials, fracture properties, **21-103**  
  agglomeration processes, **21-82**  
    breakage and attrition, **21-100**  
    fracture measurements, **21-101**  
    fracture properties, **21-101**  
    mechanisms of attrition and breakage, **21-102**  
  classification, **21-91**  
  growth and consolidation, **21-89**  
    deformability and interparticle forces, **21-92**  
    deformability and wet mass rheology, **21-93**  
    granule consolidation and densification, **21-99**  
    granule deformability, **21-89**  
    high agitation intensity growth, **21-96**  
    low agitation intensity, **21-95**  
    types of granule growth, **21-90**  
  paste extrusion, **21-108**  
    compaction in a channel, **21-108**  
    drag-induced flow in straight channels, **21-108**  
    paste rheology, **21-108**  
  powder compaction, **21-103**  
    compact density, **21-105**  
    compact strength, **21-105**  
    compaction cycles, **21-107**  
    compaction pressure, **21-105**  
    controlling powder compaction, **21-108**  
    hiestand tableting indices, **21-107**  
    powder feeding, **21-104**  
    stress transmission, **21-106**  
  wetting, **21-82**  
    examples of the impact of wetting, **21-86**  
    mechanics of the wetting rate process, **21-82**  
    methods of measurement, **21-83**  
    nucleation and wetting, regimes, **21-86**  
  air, dry, thermodynamic properties, **2-215**

## 2 INDEX

- air, thermodynamic properties, 2-211 to 2-214  
air conditioning:  
  equipment, 11-77 to 11-78  
  central systems, 11-77  
  load calculation, 11-77  
  unitary refrigerant-based systems, 11-77  
  ventilation, 11-76  
air cooler, wet surface, 12-17, 12-22 to 12-25  
  application, 12-24  
  configuration, 12-23  
air pollutants, general, 22-28  
  control-equipment selection, 22-36  
  effects of air pollutants, 22-31  
  estimating emissions from sources, 22-31  
  gaseous pollutants, 22-28  
  particulate pollutants, 22-29  
  source-control-problem strategy, 22-35  
air pollutants, hazardous, 22-11 to 22-12  
air quality standards, 22-6  
air spring effect, 8-86  
alarm, rate of change, 8-67  
alarms, 8-67  
algebra, elementary:  
  binomial theorem, 3-8  
  operations, 3-8 to 3-9  
  permutations, combinations, and probability, 3-10  
  progressions, 3-9 to 3-10  
  theory of equations, 3-10 to 3-11  
    cubic, 3-10  
    determinants, 3-11  
    factor theorem, 3-10  
    fundamental theorem of algebra, 3-10  
    linear, 3-10  
    quadratic, 3-10  
    remainder theorem, 3-10  
algebraic inequalities, 3-5 to 3-6  
  arithmetic-geometric inequality, 3-5  
  Carleman's inequality, 3-5  
  Cauchy-Schwarz inequality, 3-5  
  Holder's inequality, 3-5  
  Lagrange's inequality, 3-5  
  Minkowski's inequality, 3-5  
alkyl chloride, 17-17  
allocated capital, 9-10, 9-17  
alphabet, Greek, 1-18  
Ambose-Walton modification of Lee-Kesler vapor  
  pressure equations, 2-473 to 2-475  
ammonia, thermodynamic properties, 2-217  
  to 2-219  
amortization, 9-22  
amplifier network, 8-84  
anabolic, 7-31  
anaerobic fermentations, 7-18  
analog input and output channels, 8-65, 8-72  
analog signal transmission, 8-65  
analytical geometry, plane:  
  asymptotes, 3-12  
  conic sections, 3-12  
  coordinate systems, 3-11  
  parametric equations, 3-13  
  straight line, 3-11 to 3-12  
analyzer controller, 8-43  
angles and sides of triangles relations, 3-17 to 3-18  
angular displacement, 8-89  
annular liquid separation bed, 16-67  
anode, electrochemical reactions, 7-32  
Antoine equation, 12-5  
API gravity, 13-99  
approximation identities, mathematical, 3-43  
argon, thermodynamic properties, 2-221 to 2-223  
argon-nitrogen-oxygen system, liquid vapor  
  equilibrium data, 2-224 to 2-227  
aromatic extracting, simplified, 15-9  
Arrhenius equation, 7-6  
ASME boiler and pressure code section VIII, division 1, quick reference guide, 10-153 to 10-154  
ASME B16.5 flanges, dimensions of, 10-83 to 10-86  
assets, 9-5  
  current assets, 9-5  
  accounts receivable, 9-5  
  cash, 9-5  
  cash equivalents, 9-5  
  inventories, 9-5  
  marketable securities, 9-5  
  prepaid expenses, 9-5  
  fixed assets, 9-5  
  net property and equipment, 9-5  
  total property, plant, and equipment, 9-5  
  total assets, 9-5, 9-6  
Assman psychrometer, 12-6  
asymptotic solution, 16-35  
atmosphere, international standard, thermodynamic  
  properties, 2-228  
atmospheric dust concentrations, 17-52  
atomizers, 14-94  
autocatalysis, 7-16  
autocatalytic reaction, 7-16  
autoignition temperature, 2-515 to 2-517  
automation, 8-94  
automation projects, 8-29  
autotune function, 8-26  
auto-tuning, 8-69  
azeotropic mixtures:  
  definition of, 13-6  
  heterogenous, 13-6 to 13-7, 13-68  
  homogenous, 13-6 to 13-7, 13-68  
  maximum boiling, 13-7, 13-68  
  minimum boiling, 13-7, 13-68  
  reactive, 13-94, 13-95  
backpressure, 8-78  
baffle towers, 15-80  
baffles, trays, 14-35  
balance sheet, 9-4, 9-5, 9-6  
bancroft point, 13-68  
band compression factor, 16-45  
BASIC, 8-70  
batch dryers, control, 8-46  
batch process control, 8-46  
batch reactor control, 8-51  
batch reactors, 7-34  
  electrical or thermal conductivity, 7-31  
  light adsorption, 7-34  
  polarography, 7-34  
  viscosity of polymerization, 7-34  
bearings, 10-65 to 10-67  
  thrust bearings, 10-66  
    plain washer, 10-67  
    taper land, 10-67  
    temperature characteristics, 10-68  
    tilting pad, 10-67  
  thrust-bearing power loss, 10-67  
  types of bearings, 10-65  
    circumferential grooved, 10-65  
    comparison of, 10-66  
    cylindrical bore, 10-65  
    lemon bore or elliptical, 10-66  
    offset halves, 10-66  
    plain journal, 10-65  
    pressure or pressure dam, 10-65  
    three-lobe, 10-66  
    tilt-pad, 10-66  
bed profiles, 16-33  
beds of solids, 6-39 to 6-40  
  fixed beds of granular solids, 6-39  
  fluidized beds, 6-40  
  porous media, 6-39 to 6-40  
  tower packing, 6-40  
bellows element, 8-59  
benzene:  
  Antoine vapor pressure, 13-14  
  thermodynamic properties, 2-229 to 2-230  
  Txy diagram, 13-8  
  x-y diagram, 13-8  
Bernoulli relationship, flow control calculation, 8-80  
Bernoulli's equation, 8-9  
Bhelousov-Zhabotinsky reaction, 7-39  
binary input, digital technology, 8-70  
binary signal, pseudo random, 8-12  
biocatalysis, 7-18  
biochemical reactions, 7-30  
  balanced growth, 7-30  
  mechanism, 7-31  
  yield coefficients, 7-31  
biochemical separation processes:  
  background, 20-71 to 20-73  
  final purification, 20-79 to 20-83  
    alternative columns, 20-82  
    chromatographic development, 20-81  
    to 20-82  
  column packings, 20-82  
  scale-up of liquid chromatography, 20-83  
  schematic, 20-80  
  sequencing of chromatographic steps, 20-83  
  types of chromatography, 20-79 to 20-81  
initial product harvest and concentration, 20-73  
  to 20-76  
  cell disruption, 20-73 to 20-74  
  clarification methods, 20-75 to 20-76  
  protein refolding, 20-74 to 20-75  
  selection of unit operation, 20-76  
initial purification:  
  adsorption, 29-78  
  liquid-liquid partitioning, 20-76 to 20-78  
  membrane ultrafiltration, 20-78  
  precipitation, 20-76  
  integration of unit operations, 20-84  
  product polishing and formulation, 20-83  
  drying, 20-83  
  lyophilization, 20-83  
biological APC technologies, 22-48 to 22-51  
  biofilters, 22-50  
  biofiltration, 22-48  
  bioscrubbers, 22-50  
  biotrickling filters, 22-51  
biological systems, 7-30  
  kinetics, 7-31  
  mechanisms, 7-31  
  yield coefficients, 7-31  
biomass:  
  biochemical reactions, 7-30  
  *See also* solid wastes  
bioreactors, 7-18, 7-35  
  batch, 7-35  
  CSTR, 7-35  
  chemostat, 7-35  
  dilution rate, 7-35  
  semibatch, 7-35  
Biot number, 16-30  
BIPS binary interaction parameters, 13-13  
black-body behavior, 8-58  
blending:  
  chemical reactions, 18-16  
  high viscosity systems, 18-15  
block diagrams, use in modeling, 8-8  
block-diagram analysis, 8-22  
blowdown calculation, 12-20  
boil up/bottom flow ratio, 8-43  
boilers, 24-35 to 24-41  
  design issues, 24-36  
  circulation and heat transfer, 24-36

- boilers (*Cont.*):  
 fluidized-bed:  
 bubbling FBCs, 24-39  
 circulating FBCs, 24-40 to 24-41  
 industrial:  
 boiler band, 24-37  
 design parameters and criteria, 24-38  
 fire-tube boilers, 24-39  
 fuel consumption, 24-38  
 package boilers, 24-39  
 solid-waste fuels burned, 24-38  
 utility steam generators:  
 economics, 24-37  
 fuel characteristics, 24-37  
 reheat cycle, 24-37  
 steam-generator circulation system, 24-37  
 superheaters and reheaters, 24-37
- boiling, 5-14 to 5-15  
 coefficients, 5-15  
 film boiling, 5-15  
 maximum heat flux, 5-15  
 nucleate boiling, 5-14 to 5-15  
 pool boiling, 5-14  
 boiling point:  
 curve, 13-101  
 initial (IBP), 13-99  
 true (TBP), 13-100  
 boiling point, normal, 2-471 to 2-476  
 calculation methods, 2-471 to 2-473  
 Nannoolal method, 2-471 to 2-473  
 Pailhes method, 2-472  
 group contributions for Nannoolal method, 2-474  
 intermolecular interaction corrections, 2-476  
 bolometer, detector, 8-62  
 bonnets, 8-75  
 booster relays, 8-90  
 bottom products, 8-42  
 boundary layer flows, 6-40 to 6-41  
 continuous cylindrical surface, 6-41  
 continuous flat surface, 6-41  
 cylindrical boundary layer, 6-41  
 flat plate, zero angle of incidence, 6-40 to 6-41  
 bourdon tube, 8-57, 8-59  
 broad-spectrum noise, 8-81  
 bromine, saturated, thermodynamic properties, 2-231  
 bubble point temperature, def, 13-15  
 bubble tube, 8-61  
 budget control, 9-10  
 burst mode, 8-87  
 butanes:  
 K-value versus pressure, 13-12  
 thermodynamic properties, 2-232 to 2-233  
 butanol, 13-86  
 Antoine vapor pressure, 13-14  
 BIP data, 13-13  
 VLE data, 13-9  
 butene:  
 cis-2:  
 thermodynamic properties, 2-236 to 2-237  
 thermodynamic properties, 2-234 to 2-235  
 Butler-Volmer equation, electrochemical reaction, 7-33  
 butyric acid, BIP data, 13-13  
 butterfly valve, 8-75  
 bypass valve, 8-90
- calcinations, 17-17 to 17-18  
 calciner, fluid-bed, 17-18  
 calibration of a measurement device, 8-55  
 calorimetry, 7-35  
 capacitance probes, 8-60  
 capillary flow, 12-26
- capital cost estimation, 9-10 to 9-17  
 carbon dioxide:  
 absorption in NaOH, 14-21  
 solubility in MEA, 14-8  
 thermodynamic properties, 2-240 to 2-244, 2-200  
 carbon  $\frac{1}{2}$ Mo steel (group 1.5 materials), pressure-temperature ratings, 10-109  
 carbon steel (group 1.1 materials), pressure-temperature ratings for, 10-108  
 carbon steel materials, tabular values for minimum temperatures without impact testing for, 10-128 to 10-129  
 carbon tetrachloride:  
 Antoine vapor pressure, 13-14  
 BIP data, 13-13  
 saturated:  
 thermodynamic properties, 2-245  
 carbon tetrafluoride (R14), saturated thermodynamic properties, 2-245  
 carbonyl sulfide, thermodynamic properties, 2-246 to 2-247  
 cascade control, 8-24  
 cascade factor, 12-74  
 cash flow, 9-27  
 cumulative cash position plot, 9-28  
 example of, 9-11, 9-29  
 cumulative cash position, 9-27  
 example of, 9-25, 9-28  
 catabolic pathway, biological reactions, 7-31  
 catalysis, 7-9, 8-44  
 solid, 7-16  
 catalyst deactivation, 7-22  
 catalyst poisoning, 7-22  
 catalysts, solid, 7-35  
 effectiveness, 7-35  
 catalytic cracking, 7-16  
 catalytic reactions, 7-9  
 biocatalysis, 7-18  
 fluid-solid, 7-16  
 gas-liquid solid, 7-28  
 gas-solid, 7-19  
 heterogeneous, 7-10  
 homogeneous, 7-10  
 solid, 7-16  
 solid-liquid, 7-18  
 catalytic reactors:  
 fixed beds, 19-30 to 19-33  
 heterogeneous 1D model, 19-32  
 heterogeneous 2D model, 19-32 to 19-33  
 homogeneous 1D model, 19-31  
 homogeneous 2D model, 19-31 to 19-32  
 thermal conductivity, 19-32  
 wall heat transfer, 19-32  
 fluidized beds, 19-33 to 19-36  
 monolith catalysts, 19-27 to 19-30  
 types of, 19-29  
 moving beds, 19-33  
 examples, 19-35  
 multifunctional reactor, 19-36  
 slurry reactors, 19-36  
 transport reactors, 19-36  
 wire gauzes, 19-27  
 cathode, chemical reduction at, 7-32  
 cation and anion exchangers, 16-15  
 cavitations, pump behavior, 8-82  
 centrifugal filtration:  
 costs:  
 purchase, 18-140  
 installation, 18-141  
 maintenance, 18-142  
 labor, 18-142
- centrifugal filtration (*Cont.*):  
 filtering, 18-140  
 moisture, residual, 18-139  
 rate of filtration, 18-138  
 sedimentation, 18-140  
 theory, 18-138  
 centrifugal force:  
 industrial centrifuges, 18-118  
 variation w/rpm, 18-119  
 centrifugal pump, 8-91  
 centrifugal separation, principles diagram, 18-116  
 centrifugal separator, 15-92  
 centrifuge equipment, photos and sketches:  
 bottom unloading vertical basket, 18-130  
 bowls, disk stack, 18-123  
 cylindrical-conical screen-bowl, 18-126  
 disc stack, 18-122  
 installation, vertical basket, 18-130  
 inverted filter, 18-133 to 18-134  
 peeler cross section, 18-131  
 pharma peeler, 18-133  
 pusher cross section, 18-136  
 pusher process steps, 18-137  
 pusher product moisture gradient, 18-138  
 pusher solids transport representation, 18-137  
 scroll screen, 18-135  
 sedicanter, 18-125  
 siphon peeler cross section, 18-132  
 sorticanter, 18-126  
 three-phase decanter, 18-125  
 top unloading vertical basket, 18-129  
 top-suspended, vertical, 18-131  
 two-phase decanter, 18-122, 18-124  
 centrifuge equipment:  
 batch filtering centrifuges, 18-127 to 18-133  
 bottom unloading vertical basket centrifuges, 18-128  
 horizontal peeler centrifuge, 18-29 to 18-131  
 inverting filter centrifuge, 18-133  
 pharma peeler centrifuge, 18-132 to 18-133  
 pressurized siphon peeler centrifuge, 18-132  
 siphon peeler centrifuge, 18-131 to 18-132  
 top suspended vertical centrifuges, 18-128 to 18-129  
 top unloading vertical basket centrifuges, 18-128  
 continuous filtering centrifuges, 18-133  
 centrifugal filtration theory, 18-138  
 cylindrical or conical pusher centrifuge, 18-138  
 multi-stage pusher centrifuges, 18-136  
 single-stage pusher centrifuges, 18-136  
 costs, 18-140 to 18-142  
 expression, 18-143 to 18-146  
 filtering centrifuges, 18-127  
 introduction, 18-115  
 general principles, 18-115 to 18-118  
 cake conveyance power, 18-117  
 cake dryness, 18-116  
 cake liquid saturation, 18-116  
 cake porosity, 18-116  
 centrifuge rotor stress, 18-117  
 centripetal and centrifugal acceleration, 18-115  
 clarification, 18-115  
 classification, 18-115  
 Coriolis acceleration, 18-115  
 critical speeds, 18-117  
 dewatering or deliquoring, 18-116  
 Ekman layers, 18-115  
 Ekman number, 18-115  
 feed acceleration power, 18-117  
 g-acceleration, 18-117  
 g-level, 18-115  
 momentum transfer, 18-115

## 4 INDEX

- centrifuge equipment, general principles (*Cont.*):  
performance criteria, 18-116  
polymer dosage, 18-116  
power consumption, 18-16  
recovery, 18-116  
Rossby number, 18-115  
sedimentation and filtering centrifuges, 18-115  
solids purity, 18-117  
thickening, 18-115  
throughput capacity, 18-117  
vibrational harmonics, 18-117 to 18-118  
volumetric and solids throughput, 18-117  
wash ratio, 18-117  
yield, 18-17
- sedimentation centrifuges, 18-118 to 18-127  
Ambler's sigma factor, 18-127  
cake-slurry interface, 18-120  
centrifugal gravity, 18-118  
continuous centrifugal sedimentation theory, 18-126 to 18-127  
decanter centrifuges, 18-121 to 18-125  
disc nozzle centrifuges, 18-120 to 18-121  
imperforate bowl test, 18-119 to 18-120  
knife-discharge centrifugal clarifiers, 18-120 to 18-121  
liquid-slurry interface, 18-120  
manual disc stack centrifuges, 18-120  
multichamber centrifuges, 18-120  
screenbowl centrifuges, 18-125 to 18-126  
sedicanter, 18-125  
self-cleaning disc centrifuges, 18-120  
solids concentration, 18-120  
spin-tube tests, 18-118 to 18-119  
transient centrifugation theory, 18-120  
tricanter centrifuges, 18-125  
tubular-bowl centrifuges, 18-120  
yield stress, 18-119  
selection, 18-140
- cesium, saturated, thermodynamic properties, 2-248
- chain or tape float gauge, 8-60
- chain reaction mechanism, 7-14
- chain reactions, 7-14
- change of state alarm, 8-67
- charcoal, 24-7
- Chebyshev method, 12-18
- check valves, 8-79
- chemical composition analyzers V, 8-62
- chemical dynamics determination, 7-38
- chemical equilibrium, 7-7  
gas phase, 7-17
- chemical reaction:  
bimolecular, 7-5  
stoichiometry, 4-35  
trimolecular, 7-5  
unimolecular, 7-5
- chemical reactors, control of, 8-44
- chemical sensors, 8-63
- chemical systems, 7-30
- chemisorption, 16-4
- chemostat, 7-31
- Chilton-Colburn analogy, 12-6, 12-53
- chlorine:  
enthalpy-pressure, 2-250  
saturated:  
thermodynamic properties, 2-249
- chloroform:  
Antoine vapor pressure, 13-14  
residue map, 13-79  
VLE data, 13-7 to 13-9  
saturated:  
thermodynamic properties, 2-251
- choke, 8-80
- chopped light system, 8-62
- chromatographic analyzers, 8-62
- chromatographs, 8-66
- chromatography:  
displacement development, 16-39  
elution, 16-38  
curves, 16-43  
gradient, 16-38, 16-44  
isocratic, 16-38, 16-42, 16-47  
frontal analysis, 16-39  
Gaussian peak, 16-41 to 16-42  
ion exchange, 16-45  
operation, 16-38  
peak asymmetry factor, 16-41  
peak skew, 16-41  
plate models, 16-42  
resolution, 16-41  
reversed-phase, 16-45  
Sanmatsu Kogyo process, 16-58  
tailing peaks, 16-41
- circular trigonometric functions, 3-16 to 3-17  
common angle values, 3-16  
identities, 3-17  
plane trigonometry, 3-16  
single angle relations, 3-16 to 3-17
- clarifiers:  
instrumentation, 18-78  
types:  
circular, 18-74  
clarifer-thickener, 18-74  
inclined plate, 18-75  
rectangular, 18-74  
secondary, industrial waster, 18-74  
solids contact, 18-75
- closed loop, 8-13
- closed-circuit cooling, 12-24 to 12-25
- closed-loop system, general control system, 8-5
- closed-loop time constant, 8-74
- coal, 24-4 to 24-6  
classification, 24-4  
coal-ash:  
characteristics, 24-5  
composition, 24-6  
fouling, 24-6  
composition, 24-5  
as-received, 24-5  
dry, ash-free, 24-5  
moisture-free, 24-5  
ultimate analysis, 24-5  
heating value, 24-5  
mercury emissions, 24-5  
origin, 24-4  
physical properties:  
bulk density, 24-6  
free-swelling index, 24-6  
Hargrove grindability index, 24-6  
mean specific heat, 24-6  
size stability, 24-6  
reserves by region, 24-5  
sulfur content, 24-5
- coal char, 24-7
- coal conversion, 24-12 to 24-21  
gasification. *See* coal gasification  
liquefaction. *See* coal liquefaction  
production diagram, 24-13
- coal gasification, 24-12 to 24-16  
background, 24-12  
chemical reactions, 24-14  
coal-derived gas compositions, 24-13  
cost of gasification-based power systems, 24-16  
current technology, 24-16  
gasification-based power systems, 24-14 to 24-16  
gasifier types:  
entranced bed, 24-14  
fluidized bed, 24-14  
moving bed, 24-14  
temperature profiles, 24-15  
theoretical considerations, 24-12 to 24-14
- coal liquefaction, 24-16 to 24-21  
background, 24-16  
chemicals from syngas, 24-20 to 24-21  
coal-oil coprocessing, 24-18 to 24-19  
commercial operations, 24-19, 24-21  
direct hydrogenation, 24-17  
direct liquefaction 24-17 to 24-19  
conditions and product yields, 24-18  
kinetics, 24-17 to 24-18  
process diagram, 24-17  
Exxon donor solvent process, 24-18
- coating flows, 6-42 to 6-43
- cogeneration, 24-44 to 24-45  
background, 24-44  
characteristics for heat engines, 24-44  
choice of fuel, 24-44  
typical systems, 24-45
- coke, 24-6 to 24-7  
description, 24-6  
properties table, 24-6  
types of:  
foundry, 24-6  
high-temperature, 24-6  
low-temperature, 24-6  
medium-temperature, 24-6  
needle, 24-7  
petroleum, 24-6 to 24-7  
pitch, 24-6
- collection efficiency, 17-23, 17-27
- collision theory, 7-6
- colorimetric detection selective oxidation, 8-62
- column pressure, 8-43
- columns, tray and packed bed, pollutants, 22-38
- combined wave, 16-32
- combustion, background:  
available heats, 24-22  
excess air, 24-22  
flame speed, 24-23  
flame temperature, 24-22 to 24-23  
flammability limits, 24-23  
products, 24-22  
theoretical oxygen and air, 24-21 to 24-22  
various fuel characteristics, 24-23
- combustion, gaseous fuels, 24-32 to 24-35  
gas burners:  
fully premixed, 24-33  
nozzle-mix, 24-33  
partially premixed, 24-33  
staged, 24-33  
system illustrations, 24-33 to 24-35
- combustion, liquid fuels, 24-31 to 24-32  
atomizers, 24-31 to 24-32  
illustrations of different types, 24-31 to 24-32  
oil burners, 24-32  
pressure atomizers, 24-31  
twin-fluid, 24-32  
dew point vs. sulfur content, 24-31
- combustion, solid fuels:  
fluidized-bed combustion. *See* fluidized-bed combustion  
fuel-bed firing. *See* fuel-bed firing  
suspension firing. *See* suspension firing  
combustion systems, pollutants, 22-38
- commodity plants, control of, 8-47
- comparators, use in control, 8-71
- comparison of alternative investments, 9-35  
cash flow method, 9-36  
net present worth method, 9-36  
uniform annual cost (USC) method, 9-36
- complex reactions. *See* global reactions
- complex variables, 3-27 to 3-29
- compressibilities:  
composition of selected refrigerant mixtures, 2-143  
liquids, 2-145, 2-144

- compressibilities (*Cont.*):  
 R 407A, compressibility factors, 2-143  
 R 407B, compressibility factors, 2-143  
 solids, 2-146, 2-144
- compressibility factor, 7-8
- compressible flow, 6-22 to 6-26  
 adiabatic flow with friction in a duct of constant cross section, 6-24  
 adiabatic frictionless nozzle flow, 6-23 to 6-24  
 convergent/divergent nozzles (De Laval nozzles), 6-24 to 6-26  
 isothermal gas flow in pipes and channels, 6-22 to 6-23  
 Mach number and speed of sound, 6-22
- compression, gas, 10-42  
 adiabatic calculations, 10-44  
 efficiency curve, 10-45  
 polytropic curve, 10-46  
 work, 10-45
- compression processes, thermodynamics, 4-16 to 4-17
- compressors, 10-40 to 10-48  
 high-pressure, 10-47  
 metallic diaphragm, 10-48  
 performance characteristics of, 10-45  
 reciprocating compressors, 10-45  
 clearance unloaders, 10-47  
 closed-suction unloaders, 10-47  
 control devices, 10-46  
 five-step control, 10-47  
 nonlubricated cylinders, 10-47  
 open inlet-valve unloaders, 10-47  
 piston-rod packing, 10-48  
 single-stage, double-acting water-cooled compressor, 10-47  
 three-step control, 10-47  
 valve losses, 10-46
- selection, 10-42  
 theory of, 10-42  
 adiabatic, 10-42  
 isothermal, 10-42  
 polytropic, 10-42  
 types of, 10-44
- compressors, centrifugal problems, 10-67  
 failure, 10-69  
 barrel-type compressor, 10-69  
 fouling, 10-68  
 air compressors, 10-68  
 blade coating, 10-68  
 prevention techniques, 10-68  
 impeller problems, 10-69  
 journal bearing failures, 10-70  
 rotor thrust problems, 10-69  
 seal problems, 10-70  
 thrust bearing failures, 10-70  
 causes, 10-70  
 wear points in the bearing, 10-70
- compressors, continuous-flow, 10-52 to 10-57  
 axial-flow, 10-54 to 10-56  
 centrifugal, 10-52  
 choke or stonewall, 10-52  
 compressor map, 10-53  
 configurations, 10-53, 10-54  
 fabrication techniques, impellers, 10-54  
 impeller fabrication, 10-54  
 pressure and velocity through, 10-52  
 surge, 10-52
- positive-displacement, 10-56  
 reciprocating, 10-56  
 rotary, 10-56
- rotary, 10-56  
 liquid-piston type, 10-56  
 screw-type, 10-56  
 sliding-vane type, 10-56  
 straight-lobe type, 10-56
- computational fluid dynamics, 18-26, 6-47 to 6-49
- computer controllers, 8-72  
 personal, 8-69, 8-73
- computerized cost estimation, 9-17  
 ASPENTECH ICARUS 2000, 9-17
- computers in process control, 8-5  
 concentration types, 7-8  
 mole fractions, 7-8  
 partial pressures, 7-8  
 volumetric concentration, 7-8
- condensation, 5-12 to 5-14  
 coefficients, 5-12 to 5-14  
 banks of horizontal tubes, 5-14  
 horizontal tubes, 5-14  
 vapor shear controlling, 5-14  
 vertical intube condensation, 5-14  
 mechanisms, 5-12 to 5-14  
 dropwise, 5-12  
 film-type condensation, 5-12, 5-13  
 scrubbing, 17-39  
 Stefan-flow mechanism, 17-39
- condensers, pollutants, 22-39
- conduction, 5-3 to 5-7  
 steady-state, 5-3 to 5-6  
 heat source, 5-5  
 one-dimensional, 5-3 to 5-4  
 resistances, 5-5  
 two- and three-dimensional, 5-5 to 5-6  
 unsteady-state, 5-6 to 5-7  
 one-dimensional, 5-6 to 5-7  
 two- and three-dimensional, 5-7
- conductometric analysis, 8-63
- confidence level, 7-37
- conjugate gradient, multivariable optimization, 8-34
- conservation of energy, basis for modeling, 8-6  
 conservation of mass, basis for modeling, 8-6, 8-80  
 conservation of momentum, basis for modeling, 8-6
- constant-rate period, 12-26
- constants:  
 fundamental physical, 1-20  
 gas law, values of, 1-17
- constrained optimization, 8-34
- contact discontinuity, 16-32
- continuous measurements, 8-54
- continuous models, use in control, 8-8
- continuous variable approximation method, 7-30
- control alarm, 8-73
- control limits:  
 lower and upper, 8-36  
 specified, 8-38
- control network, 8-70
- control switches, 8-49
- control systems design and simulation, 8-31
- control valves, 8-74
- controller:  
 comparison, 8-16  
 design, 8-31  
 multiloop, 8-72  
 performance, 8-17, 8-73  
 reliability and application trends, 8-73  
 single-loop, 8-69, 8-72 to 8-73  
 tuning, 8-16
- controlling rate factor, determination of, 16-25
- convection, 5-7 to 5-12, 12-26  
 forced convection, 5-9 to 5-12  
 coiled tubes, 5-10  
 external flows, 5-10  
 falling films, 5-11  
 fin efficiency, 5-11 to 5-12  
 finned tubes, 5-11  
 horizontal tubes, 5-11 to 5-12  
 noncircular ducts, 5-9 to 5-10  
 round tubes, 5-9
- convection, forced convection (*Cont.*):  
 tube banks, 5-10 to 5-12  
 vertical tubes, 5-12  
 non-newtonian flows, 5-12  
 circular tubes, 5-12
- conversion factors:  
 calculations, U.S. customary to SI units, 1-21  
 common, alphabetical listing of, 1-14 to 1-16  
 factors:  
 common, 1-17  
 metric, exact numerical multiples of SI units, 1-12 to 1-13  
 U.S. customary and commonly used units to SI units, 1-3 to 1-11
- formulas:  
 kinematic-viscosity, 1-17  
 temperature, 1-18
- SI, 1-2
- conveyor dryers, 8-46
- cooling towers, 12-17 to 12-22  
 applications, 12-21  
 cooling pond, 12-21  
 cooling range, 12-20  
 cross-flow tower, 12-19  
 counterflow, 12-19  
 cycles of concentration, 12-20  
 fogging and plume abatement, 12-21  
 forced-draft tower, 12-19  
 horsepower chart applications, 12-20  
 induced-draft tower, 12-19  
 mechanical draft tower, 12-19  
 natural draft tower 12-21  
 new technologies, 12-21  
 spray pond, 12-21  
 theory, 12-17  
 thermal performance, 12-21  
 time of contact, 12-19  
 tower characteristic, 12-18  
 water makeup, 12-20
- copolymerization, 7-29 to 7-30
- Coriolis mass flowmeters, 8-59 to 8-60
- corporate information systems, 8-69
- corrosion:  
 anodic protection, 25-10 to 25-11  
 cathodic protection, 25-10  
 concentration effects, 25-9 to 25-10  
 dealloying, 25-6  
 design considerations, 25-10  
 embrittlement, 25-16  
 EMF, 25-17  
 fatigue, 25-6  
 film, 25-9  
 fluid, 25-4 to 25-6  
 cavitation, 25-3  
 crevice, 25-4  
 erosion, 25-5  
 fretting, 25-6  
 galvanic, 25-4, 25-16  
 hydrogen attack, 25-6  
 hydrogen embrittlement, 25-6  
 intergranular, 25-5  
 liquid-metal, 25-5  
 oxygen-concentration cell, 25-4  
 stress cracking, 25-5  
 velocity acceleration, 25-6
- graphitic, 25-6
- high-temperature attack, 25-9 to 25-10  
 expansivity, 25-9  
 structural stability, 25-9
- inhibitors, 25-10
- laboratory testing, 25-12 to 25-24  
 AC impedance, 25-23  
 apparatus, 25-14  
 cathodic depolarization, 25-19  
 CBD, 25-20

## 6 INDEX

- corrosion, laboratory testing (*Cont.*):

      - performance curves, **17-38 to 17-39**
      - performance models, **17-37 to 17-39**
      - pressure drop, **17-31 to 17-32**
    - dry scrubbing, **17-43 to 17-45**
    - electrical precipitators, **17-55 to 17-63**
      - applications, **17-57**
      - charging of particles, **17-56**
      - coal combustion fly-ash, **17-59**
      - collection efficiency, **17-57**
      - conditioning agents, **17-59**
      - current flow, **17-56**
      - electric wind, **17-56**
    - dust collection, electrical precipitators (*Cont.*):
      - field strength, **17-55**
      - high-pressure, high-temperature EP, **17-57 to 17-59**
      - particle mobility, **17-56 to 17-57**
      - potential and ionization, **17-55 to 17-56**
      - power supply, **17-62**
      - rapping, **17-61**
      - resistivity issues, **17-59**
      - types of, **17-60 to 17-63**
    - fabric filters (bag filters with baghouses), **17-46 to 17-51**
      - collection efficiency, **17-49 to 17-51**
      - filter fabrics, **17-49**
      - filter types, **17-47 to 17-49**
      - gas pressure drops, **17-46 to 17-47**
      - granular-bed filters, **17-51 to 17-52**
      - Kozeny-Carman equation, **17-46**
    - gravity settling chambers, **17-28**
    - impingement separators, **17-28**
    - mechanical centrifugal separators, **17-36**
    - mechanisms, **17-26 to 17-27**
    - sonic or acoustic agglomeration, **17-26**
    - Stefan flow, **17-26**
    - particulate scrubbers, **17-36 to 17-43**
      - performance, **17-27**
      - purpose of, **17-24**
    - scrubber types:
      - cyclone, **17-42**
      - ejector venturi, **17-40**
      - electronically augmented, **17-43**
      - fiber-bed, **17-43**
      - mechanical, **17-43**
      - mobile-bed, **17-42 to 17-43**
      - packed-bed, **17-42**
      - plate tower, **17-42**
      - self-induced spray, **17-41**
      - spray, **17-41 to 17-42**
      - venturi, **17-40 to 17-41**
  - dust collector design, **17-27**
  - polydisperse test dust, **17-27**
  - dust separation, **17-14**
    - cyclones, **17-14 to 17-16**
    - cyclone arrangements, **17-15**
    - solids return seals, **17-15**
  - dynamic compensation, in control analysis, **8-22**
  - dynamic models, use in control, **8-30**
    - fitting to experimental data, **8-12**
    - simulation, **8-7**
- Eckert pressure-drop correlation, packed towers, **14-58**
- economic journal, **9-4**
  - account title, **9-4**
  - example of, **9-5**
  - invoices, **9-4**
  - receipts, **9-4**
- economic project, execution and analysis, **9-41 to 9-53**
- economizers:
  - acid dew point, **24-52**
  - background, **24-51**
  - boiler thermal efficiency, **24-52**
  - condensing, **24-52 to 24-54**
  - collateral combustion emissions, **24-54**
  - efficiency graph, **24-53**
  - environmental benefits, **24-54**
  - flue gas pollutant removal, **24-54**
  - flue gas sensible heat, **24-52**
  - fuel avoidance, **24-52**
  - technologies, **24-52 to 24-54**
  - water vapor latent heat, **24-52**
  - conventional, **24-52**
  - water dew point, **24-52**

- EFV, equilibrium flash distillation, 13-102
- ejectors, 10-57 to 10-58
- condensers, 10-57
    - aftercondenser, 10-57
    - direct-contact (barometric), 10-57
  - performance, 10-57
    - constant-area mixing, 10-57
    - use of, 10-58 to 10-58
- elastic element method, 8-59
- elasticity, modulus of, nonmetals, 10-126
- electric field, separations based on:
- dielectrophoresis, 20-23 to 20-27
    - applications, 20-25 to 20-27
    - field warpage, 20-26
    - limitations, 20-25
    - principle and theory, 20-24
  - electrofiltration, 2-21 to 20-23
    - concepts, 20-21
    - cross-flow, 20-22
    - theory, 20-22
  - electrophoresis, 20-20 to 20-21
    - theory, 20-19 to 20-20
    - permittivity, 20-20
    - zeta potential, 20-20
- electrical efficiency, percent, 8-92
- electrical precipitators, 17-55 to 17-63
- alternating current precipitators, 17-63
  - charging of particles, 17-56
  - collection efficiency, 17-57
  - conditioning agents, 17-59
  - corona, 17-55 to 17-63

## 10 INDEX

- equipment, safety, process design and operation,
    - key procedures (*Cont.*):
    - key performance indicators, **23-110**
    - preparation of equipment for maintenance, **23-109**
  - pressure relief systems, **23-74**
    - codes, standards, and guidelines, **23-75**
    - pressure relief devices, **23-76**
    - reactive systems, **23-77**
    - relief design scenarios, **23-75**
    - relief system flow capacity, **23-78**
    - sizing of pressure relief systems, **23-77**
    - terminology, **23-74**
  - safety instrumented systems, **23-102**
    - definitions, **23-102**
    - engineering, installation, commissioning, and validation (EICV), **23-104**
    - hazard and risk analysis, **23-103**
    - operating basis, **23-104**
    - process and safety requirements specification, **23-104**
  - security, **23-104**
    - countermeasures and security risk management concept, **23-108**
    - defining the risk to be managed, **23-107**
    - security management system, **23-109**
    - security strategies, **23-108**
    - security vulnerability assessment, **23-106**
    - SVA methodologies, **23-106**
    - terminology, **23-104**
    - threats of concern, **23-106**
  - storage and handling of hazardous materials, **23-97**
    - basic design strategies, **23-98**
    - causes, loss of containment, **23-102**
    - established practices, **23-98**
    - maintaining mechanical integrity, containment system, **23-102**
    - release detection and mitigation, **23-102**
    - site selection, layout and spacing, **23-99**
    - storage, **23-99**
  - Ergun equation, **17-44**
  - error, normally distributed, **7-37**
  - ethane:
    - K-value versus pressure, **13-12**
    - thermodynamic properties, **2-263** to **2-264**
  - ethanol:
    - activity coefficient plot, **13-14**
    - Antoine vapor pressure, **13-14**
    - BIP data, **13-13**
    - VLE data, **13-7**
    - thermodynamic properties, **2-265** to **2-266**
  - ethernet protocols, **8-70**
  - ethyl alcohol, aqueous, thermodynamic properties, **2-267**
  - ethylacetate:
    - Antoine vapor pressure, **13-14**
    - BIP data, **13-13**
    - VLE data, **13-7** to **13-8**
  - ethylene, thermodynamic properties, **2-268** to **269**
  - ethylene glycol, VLE data, **13-7**
  - Euler integration method, **8-7**
  - evaporation, **12-26**
  - evaporation load, **8-46**
  - evaporative cooling, **12-17** to **12-25**
  - evaporators, **8-45**, **11-110** to **11-121**
    - accessories, **11-119** to **11-121**
    - condensers, **11-119**
    - salt removal, **11-120**
    - vent systems, **11-120**
  - arrangement of, **11-116** to **11-118**
    - forward-feed, **11-117**
    - heat recovery systems, **11-117**
    - mixed feed, **11-117**
  - evaporators, arrangement of (*Cont.*):
    - multiple-effect evaporation, **11-116**
    - parallel feed, **11-117**
    - sea water evaporators, **11-117**
    - single-effect evaporators, **11-116**
    - thermoccompression, **11-116**
  - calculations, **11-118** to **11-119**
    - boiling temperature, **11-118**
    - flash evaporators, **11-118**
    - multi-effect evaporators, **11-119**
    - optimization, **11-119**
    - thermoccompression evaporators, **11-118**
  - co-current:
    - control of, **8-45**
  - evaporator types and applications, **11-111** to **11-114**
    - agitated film, **11-114**
    - disk or cascade, **11-114**
    - flash, **11-114**
    - forced circulation, **11-111**
    - horizontal tube, **11-113**
    - long-tube vertical, **11-112**
    - miscellaneous forms of heating surface, **11-114**
    - short-tube vertical, **11-112**
    - submerged combustion, **11-114**
    - swirl flow, **11-111**
  - operation of, **11-121**
  - primary design problems, **11-110** to **11-111**
  - temperature difference, utilization of, **11-114**
  - vapor-liquid separation, **11-114** to **11-116**
- event-triggered recording, **8-88**
- exchange of sensible heat, heat exchanger control, **8-41**
- execution rate, digital controller, **8-74**
- exothermic reactions, **7-6**
- expense, manufacturing-operating, **9-18** to **9-21**
  - direct, **9-18**
  - estimation, rapid manufacturing, **9-20**
    - Holland expression, **9-20**
  - general overhead, **9-20**
  - indirect, **9-20**
  - packaging and shipping, **9-20**
  - raw material, **9-18**
  - scale up of, **9-21**
  - total manufacturing, **9-20**
  - total operating, **9-20**
  - total product, **9-20**
- expert systems, **8-26**
- expression:
  - compactable filter cakes, **18-143**
  - definition, **18-143**
- equipment:

## 12 INDEX

- flow measurements, velocity (*Cont.*):
    - flow disturbances, 10-11
    - kiel probe, 10-11
    - mean, traversing for, 10-13
    - pitometer, 10-13
    - pitot tubes, 10-11
    - pitot-static tube, 10-11 to 10-12
    - pitot-venturi tubes, 10-13
    - point velocities, 10-11
    - profile effects, 10-11
    - pulsating flow, 10-12
    - special pitot tubes, 10-13
    - variables affecting measurement, 10-1
  - flow nonuniformities, 16-21
  - flow reactors, 7-35
    - CSTRs, 7-35
    - PFRs, 7-35
  - flow through orifices, 6-22
  - flow velocity pitot tubes, special, 10-13
    - pitometer, 10-13
    - pitot-venturi, 10-13
    - shielded total-pressure tubes, 10-13
  - flowmeters, differential pressure, 10-15
    - accuracy, 10-20 to 10-21
      - abnormal velocity distribution, 10-20
      - flow pulsation, 10-20
      - minimum Hodgson numbers, 10-21
      - order of reliability for square-edged orifices and venturi tubes, 10-20
      - swirling flow, 10-20
  - elbow meters, 10-20
  - flow nozzles, 10-19
    - critical flow conditions, 10-19
    - critical flow nozzles, 10-19
    - critical pressure ratio, 10-19
    - perfect gas, 10-19
    - permanent pressure loss, 10-19
    - rate of discharge, 10-19
  - orifice meters, 10-16 to 10-18
    - annular, 10-18
    - coefficient of discharge, 10-17
    - critical flow, 10-17
    - eccentric, 10-18
    - permanent pressure loss, 10-17
    - quadrant-edged, 10-16
    - segmented, 10-18
    - sharp-edged, 10-16
    - slotted-edge, 10-16
    - square-edged, 10-16
  - venturi meters, 10-18
    - discharge coefficients, 10-19
    - Herschel-type, 10-19
    - multiventuri systems, 10-19
    - permanent pressure loss, 10-19
    - rate of discharge, 10-19
  - pressure taps, 10-16
    - corner taps, 10-16
    - pipe taps, flange taps, 10-16
    - radius taps, 10-16
    - vena contracta, 10-16
  - flowmeters, general:
    - classes, 10-23
    - classification, 10-14
    - differential pressure meters, 10-14
    - mass meters, 10-14
    - open-channel flow measurement, 10-14
    - variable-area meters, 10-14
    - velocity meters, 10-14
    - volumetric meters, 10-14

    - macroscopic equations, 6-6
    - mass balance, 6-6
    - mass balance, continuity equation, 6-7
    - mechanical energy balance, Bernoulli equation, 6-7
    - microscopic balance equations, 6-7
    - momentum balance, 6-6 to 6-7
    - stress tensor, 6-7 to 6-8
    - total energy balance, 6-7
  - fluid dynamics, dimensionless groups, 6-49 to 6-51
  - fluid flow, kinematics, 6-5 to 6-6
    - compressive and incompressible flow, 6-5
    - laminar and turbulent flow, Reynold's number, 6-6
    - one-dimensional flow, 6-5
    - rate of deformation tensor, 6-5
    - streamlines, pathlines, and streaklines, 6-5
    - velocity, 6-5
    - vorticity, 6-5 to 6-6
  - fluid flow:
    - thermodynamics:
      - duct flow, 4-15
      - pipe flow, 4-15
  - fluid mixing, 6-34 to 6-36
    - pipeline mixing, 6-36
    - stirred tank agitation, 6-35 to 6-36
  - fluidization vessel, 17-6
  - fluidized beds, uses of, 17-16 to 17-20
    - catalytic reactions, 17-16 to 17-17
      - acrylonitrile production, 17-17
      - chlorination of olefins, 17-17
      - cracking, 17-16
      - Fischer-Tropsch synthesis, 17-17
      - naphthalene oxidation, 17-17
      - polyethylene production, 17-17
  - fluidized beds, uses of (*Cont.*):
    - noncatalytic reactions, 17-17 to 17-20
      - calcination, 17-17 to 17-18
      - circulating fluidized-bed combustors, 17-19
      - improved coal combustion, 17-18 to 17-19
      - incineration, 17-19
      - pressurized fluidized-bed combustion (PFBC), 17-19
    - physical contacting, 17-20
      - adsorption-desorption, 17-20
      - coating, 17-20
      - drying, 17-20
      - heat treatment, 17-20
  - fluidized-bed combustion, 24-29 to 24-31
    - bubbling beds, 24-29
    - circulating beds, 24-29 to 24-30
    - fuel flexibility, 24-30
    - mercury emissions, 24-31
    - nitrogen oxide emissions, 24-30
    - particulate emissions, 24-30 to 24-31
    - sulfur emissions, 24-30
  - fluidized-bed seal leg, 17-14
  - fluidized-bed steam generator, 17-18
  - fluidized-bed systems, 17-2 to 17-20
    - adsorption-desorption, 17-20
    - applications, 17-16 to 17-20
    - bed height, nominal, 17-16
    - bed weight, overall, 17-16
    - bubbling or turbulent beds, 17-9
    - catalytic reactions, 17-16 to 17-17
    - circulating fluidized-bed combustors, 17-19
    - circulating or fast fluidized-beds, 17-11
    - coating, 17-20
    - cone valve, 17-13
    - dip leg, 17-15

 rheopectic, 6-5  
 shear-thinning, 6-4 to 6-5  
 time-dependent, 6-5  
 viscoelastic, 6-5  
 viscosity, 6-4
- fluids, pastes and doughs, viscous, mixing of:  
 continuous mixers, 18-34 to 18-37  
 AP Conti paste mixer, 18-35  
 Ferrel continuous mixer, 18-35  
 Holo-Flite processor, 18-35  
 Kenics static mixer, 18-36 to 18-37  
 miscellaneous continuous mixers, 18-35  
 motionless mixers, 18-36  
 pug mills, 18-35
- fluids, pastes and doughs, viscous, mixing of, continuous mixers (*Cont.*):  
 single-screw extruders, 18-34  
 Sulzer static mixer, 18-37  
 trough-and-screw mixers 18-35  
 twin-screw extruders, 18-34 to 18-35  
 equipment selection, 18-38 to 18-39  
 heating and cooling mixers, 18-38  
 intensive mixers, 18-32 to 18-34  
 Banbury mixers, 18-32 to 18-33  
 conical mixers, 18-32  
 high-intensity mixers, 18-32  
 miscellaneous batch mixers, 18-32  
 pan mullers, 18-32 to 18-34  
 plowshare mixers, 18-32  
 ribbon blenders, 18-32  
 roll mills, 18-32  
 process design considerations, 18-37 to 18-39  
 scale-up of batch mixers, 18-37 to 18-38  
 scale-up of continuous mixers, 18-38
- fluorine, thermodynamic properties, 2-270 to 2-271
- fluoSeal, type UA, 17-14
- flutec, 2-217, 2-271
- flux expressions, 5-49 to 5-50  
 Stefan-Maxwell equation, 5-50
- formal potential, electrochemical reactions, 7-32
- formation and combustion reactions, properties:  
 ideal gas sensible enthalpies, 2-201  
 ideal gas sensible entropies, 2-202  
 inorganic and organic compounds, 2-195 to 2-200
- formic acid:  
 Antoine vapor pressure, 13-14  
 BIP data, 13-13
- FORTTRAN, 8-70
- Fourier Law, 5-3  
 coefficients, 5-6  
 Fourier number, 12-34, 12-54
- free moisture content, 12-26
- free radicals, 7-14
- freezing, progressive, 20-4 to 20-5  
 applications, 20-5  
 component separation, 20-4  
 concentration-solidification curve, 20-5
- frequency-shift keying, 8-87
- frictional losses in pipeline elements, 6-16 to 6-20  
 contraction and entrance losses, 6-16 to 6-17  
 curved pipes and coils, 6-19 to 6-20  
 equivalent length and velocity head methods, 6-16  
 expansion and exit losses, 6-17  
 fittings and valves, 6-17 to 6-19
- front-end loading, 9-41 to 9-48  
 characteristics of, 9-42
- fuel cells:  
 background, 24-45  
 characteristics, 24-47  
 design principles, 24-46 to 24-47  
 efficiency, 24-46  
 polarization curves, 24-48 to 24-50  
 reaction electrochemistry, 24-47  
 schematics, 24-45 to 24-51  
 thermodynamic values, 24-47  
 types:  
 alkaline, 24-47  
 direct methanol, 24-49  
 molten carbonate, 24-49  
 phosphoric acid, 24-49  
 polymer electrolyte, 24-48 to 24-49  
 solid-oxide, 24-50
- fuel fired furnace models, 5-39 to 5-43  
 long plug flow furnace, 5-39 to 5-40  
 performance parameters, 5-39
- fuel fired furnace models (*Cont.*):  
 well-stirred combustion chamber, 5-40 to 5-43  
 dimensional approach, 5-40  
 dimensionless approach, 5-40 to 5-41  
 example, 5-41 to 5-43
- fuel-bed firing, 24-28 to 24-29  
 comparison to suspension, 24-29  
 overfeed firing stokers:  
 cross-feed (mass-burning), 24-28  
 spreader, 24-28 to 24-29  
 underfeed firing, 24-28
- fugacity:  
 coefficient:  
 definition, 4-19 to 4-20  
 evaluation of, 4-20  
 definition, 4-19 to 4-20
- function libraries, 8-50
- funicular state, 12-26
- furnaces, industrial:  
 atmosphere, 24-44  
 batch furnace, 24-43  
 continuous furnace, 24-43  
 function and process cycle, 24-42  
 heat source, 24-42  
 heating mode:  
 direct, 24-43, 24-44  
 indirect, 24-43  
 overhead, 24-43, 24-44  
 underfiring, 24-43, 24-44  
 melting furnace, 24-42  
 muffle furnace, 24-43  
 fuzzy logic control, 8-26
- ganging alarm, use in control, 8-68
- gas absorption, heat-effects, 14-15 to 14-17  
 classical adiabatic design method, 14-17  
 classical isothermal design method, 14-16  
 comparison of design methods, 14-17  
 equipment considerations, 14-16  
 operating variables, 14-16  
 rigorous design methods, 14-17  
 gas absorption solvent rate, 14-17  
 gas blanketing system, use of regulator, 8-92  
 gas chromatography, 8-62  
 gas diffusivity, 7-20  
 gas distributor, multiple-pipe, 17-8  
 gas phase reactors, 19-21  
 gas phone mass-transfer units, 14-13  
 gas pressure drops, 17-46  
 resistance coefficients, 17-46  
 gas-absorption systems, design of, 14-7 to 14-10  
 design diagrams, 14-10  
 design of absorber-stripper systems, 14-10  
 design procedures, 14-7  
 equipment, selection, 14-9  
 liquid-to-gas ratio, calculation of 14-9  
 scrubbing chlorine from air, 14-11  
 selection of solvent and nature of solvents, 14-7
- gaseous emissions, control of, 22-41  
 absorption, 22-41  
 adsorption, 22-42  
 biological APC technologies, 22-48  
 combustion, 22-44  
 condensation, 22-47  
 membrane filtration, 22-51  
 gaseous fuels, 24-10 to 24-12  
 acetylene, 24-12  
 hydrogen, 24-12  
 liquefied petroleum gas, 24-12  
 miscellaneous, 24-12  
 natural gas. *See* natural gas  
 gaseous pollutants, sources and significance, 22-30

## 14 INDEX

- gases, storage of, **10-148**
  - cavern storage, **10-149**
  - gas holders, **10-148**
  - materials, **10-149**
    - differential thermal expansion, **10-149**
  - solution of gases in liquids, **10-148**
  - storage in pressure vessels, bottles and pipe lines, **10-148 to 10-149**
- gas-in-liquid dispersions, **14-98**
  - axial dispersion, **14-111**
  - characteristics of dispersion, **14-102**
  - equipment selection, **14-106**
  - mass transfer, **14-108**
  - methods of gas dispersion, **14-102**
  - theory of bubble and foam formation, **14-100**
- gas-liquid, suspension:
  - dispersion, **18-18**
  - mass transfer, **18-19**
- gas-liquid column costs, **14-85**
  - cost of column, **14-86**
  - cost of internals, **14-85**
- gas-liquid contactors, **14-90**
  - bypassing limits spray tower performance in gas cooling, **14-91**
  - converting liquid mass-transfer data to direct contact heat transfer, **14-91**
- devolatilizers, **14-91**
  - mass transfer data, **14-91**
  - simple spray towers, **14-91**
  - spray towers as direct contact condensers, **14-91**
  - spray towers in liquid-limited systems-hollow cone atomizing nozzles, **14-91**
  - vertical reverse jet contactor, **14-90**
- gas-liquid phase dispersion, **14-86**
  - basics of interfacial contactors, **14-86**
  - droplet size, **14-88**
    - interfacial area, impact of droplet or bubble size, **14-88**
  - steady-state systems, bubbles and droplets, **14-86**
  - surface tension, effect on stability, **14-88**
  - unstable systems, froths and hollow cone atomizing nozzles, **14-88**
- gas-liquid reactors, **19-38 to 19-41**
  - absorption tables, **19-39**
  - examples, **19-41, 19-45**
- gas-liquid systems, equilibrium data sources, **14-7**
- gas-liquid-solid, suspension, **18-20**
  - loop reactors, **18-21**
- gas-solid, systems, **17-2 to 17-6**
  - air fluidization diagram, **17-2**
  - choking velocity, **17-5**
  - fluidization regime diagram, **17-4**
  - particulate fluidization, **17-6**
    - vibrofluidization, **17-6**
  - pneumatic conveying regime, **17-5**
  - simplified fluid-bed status graph, **17-4**
  - solid types, **17-2**
  - two-phase fluidization theory, **17-2**
  - upward gas flow phase diagram, **17-3**
- gas-solids separation, **17-21 to 17-63**
  - air filters, **17-52 to 17-55**
    - automatic filters, **17-54**
    - classification, **17-55**
      - high efficiency air cleaning, **17-54**
      - high efficiency particulate air, **17-54**
      - isolated fiber efficiency, **17-53**
    - air filtration theory, **17-52**
  - atmospheric pollution measurements, **17-24**
  - cyclone scrubbers, **17-42**
  - dry scrubbing, **17-43 to 17-45**
    - emission control, **17-45**
    - evaporation lifetimes, **17-45**
    - VERT filter list, **17-45**
  - gas-solids separation (*Cont.*):
    - dust collection, **17-24 to 17-28**
      - design, **17-27**
      - diffusional deposition, **17-26, 17-27**
      - electrostatic precipitation, **17-27**
      - flow-line interception, **17-26, 17-27**
      - gravity settling, **17-27, 17-28**
      - inertial deposition, **17-26, 17-27**
      - mechanisms, **17-26 to 17-27**
      - nomenclature of, **17-21 to 17-23**
      - particle deposition, **17-28**
      - performance, **17-27**
      - sonic agglomeration, **17-26**
      - thermal deposition, **17-26, 17-27**
  - gauge, pressure, manometers, **10-8**
    - bourdon-tube gauge, **10-9**
    - closed U tubes, **10-8**
      - mercury barometer, **10-8**
    - compound gauges, **10-9**
    - conditions, **10-9**
    - deadweight gauge for high pressure, **10-9**
    - differential, **10-8**
    - differential U tube, **10-8**
    - draft gauge, **10-9**
    - inclined U tube, **10-9**
    - inverted differential U tube, **10-8**
    - manometric fluid, changes of, **10-9**
    - mechanical, **10-9**
      - diaphragm, **10-9**
      - micrometers, **10-9**
    - multiplying gauges, **10-8 to 10-9**
    - open gauge, **10-8**
    - open U tube, **10-8**
    - pressure transducers with fluid-mounted diaphragms, **10-9**
    - tube size for, **10-8**
    - two-fluid U tube, **10-9**
  - gauges, pressure-measuring, types of, **10-7**
    - electric sensing devices, **10-8**
    - piezoelectric transducers, **10-8**
    - piezoresistive transducers, **10-8**
    - strain gauges, **10-8**
    - gauges based on height of liquid column, **10-7**
      - manometers, **10-7**
    - mechanical pressure gauges, **10-7**
    - Bourdon-tube, **10-7**
  - Gauss-Jordan decomposition, **7-9**
  - Geldart diagram, **12-84**
  - Geldart's classification, aeration behavior, **21-22, 21-23**
  - Geng Wang equation, **12-93**
  - genome, **7-31**
  - Gibbs energy:
    - excess:
      - models, **4-23 to 4-26**
      - fundamental property relations:
        - excess-property relation, **4-22 to 4-23**
        - and related properties, **4-22**
        - residual-property relation, **4-21 to 4-22**
      - partial molar, **4-19**
    - Gibbs energy of formation, **2-486**
    - inorganic and organic compounds, **2-196 to 2-200**
  - Gibbs-Duhem equation:
    - partial molar properties, **4-18**
  - global reactions, **7-5, 7-14**
  - globe and angle, **8-74**
  - glycolysis, **7-31**
  - golden search, **8-34**
  - granular-bed filters, **17-51**
    - cleanable granular bed filters, **17-51**
    - fixed granular bed filters, **17-51**
  - granulation, fluid bed and mixer, operating variable, **21-113 to 21-123**
  - granulation processes, control and design, **21-110**
    - controlling processing in practice, **21-113**
    - controlling breakage in practice, **21-117**
    - controlling growth and consolidation in practice, **21-117**
    - controlling wetting in practice, **21-113**
    - engineering approaches to design, **21-110**
      - scale: granulator vessel, **21-113**
      - scale: granule size and primary feed particles, **21-111**
      - scale: granule volume element, **21-112**
      - scales of analysis, **21-110**
  - granulation processes, modeling, **21-143**
  - modeling individual growth mechanisms, **21-144**
    - attrition, **21-145**
    - coalescence, **21-144**
    - layering, **21-144**
    - nucleation, **21-144**
  - population balance, **21-143**
  - simulation of granulation circuits with recycle, **21-147**
  - solution of the population balance, **21-146**
    - analytical solutions, **21-146**
    - effects of mixing, **21-146**
    - numerical solutions, **21-146**
- graphical implementations, **8-50**
- gravity decanter (horizontal), **15-98**
- gravity sedimentation operations:
  - clarifiers:
    - circular clarifiers, **18-74**
    - clarifier-thickener, **18-74**
    - inclined-plate clarifiers, **18-74**
    - industrial waste secondary clarifiers, **18-74**
    - rectangular clarifiers, **18-74**
  - clarifier and thickener testing, **18-67 to 18-68**
  - coagulant and/or flocculant selection, **18-67 to 18-68**
  - feed characterization, **18-67**
  - sedimentation testing, **18-67**
    - batch bench-scale settling tests, **18-67**
    - continuous piloting, **18-67**
    - semi-continuous bench-scale tests, **18-67**
    - specifications for design and sizing, **18-67**
  - settleable solids and sedimentation, **18-66 to 18-67**
    - types, **18-66 to 18-67**
  - testing for clarification, **18-68**
    - bulk settling, **18-68**
    - detention, **18-68**
    - solids recycle, **18-68**
  - testing for thickening:
    - determination of thickener basin area, **18-69 to 18-70**
    - optimization of flocculation conditions, **18-68 to 18-69**
    - scale-up factors, **18-70**
    - thickener-basin depth, **180-70**
    - torque requirements, **18-70 to 18-71**
    - underflow pump requirements, **18-71**
  - thickeners, **18-71 to 18-74**
    - design features, **18-73**
    - operations, **18-74**
    - types, **18-72 to 18-73**
- grinding, cost, **21-46**
- grinding and crushing, industrial practice, **21-68**
  - biological materials—cell disruption, **21-73**
  - cement, lime, and gypsum, **21-71**
    - dry-process cement, **21-71**
    - finish-grinding of cement clinker, **21-71**
    - gypsum, **21-71**
    - lime, **21-71**
    - portland cement, **21-71**
    - wet-process cement, **21-71**

- grinding and crushing, industrial practice (*Cont.*):  
 cereals and other vegetable products, **21-68**  
 flour and feed meal, **21-68**  
 soybeans, soybean cake and other pressed cakes, **21-68**  
 starch and other flours, **21-69**  
 chemicals, pigments and soaps, **21-72**  
 chemicals, **21-72**  
 colors and pigments, **21-72**  
 soaps, **21-72**  
 coal, coke and other carbon products, **21-71**  
 anthracite, **21-71**  
 bituminous coal, **21-71**  
 coke, **21-71**  
 other carbon products, **21-72**  
 fertilizers and phosphates, **21-70**  
 ores and minerals, **21-69**  
 asbestos and mica, **21-70**  
 carbonates and sulfites, **21-70**

 hazardous materials and conditions, flammability:  
 boiling-liquid expanding-vapor explosions, **23-13**  
 combustion and flammability hazards, **23-8** to **23-11**  
 aerosols and mists, **23-10**  
 estimating flammability limits, **23-8**  
 flammability diagram, **23-9**  
 flammability limit dependence on temperature, **23-8**  
 flammability limit dependence on pressure, **23-8**  
 ignition sources and energy, **23-9, 23-10**  
 limiting oxygen concentration, **23-9**  
 liquid mixtures, **23-8**  
 minimum ignition energy (MEI), **23-10**  
 vapor mixtures, **23-8**  
 dust explosions, **23-15**  
 apparatus for collecting explosion data for dust, **23-12**  
 dust explosion device, pressure data from, **23-13**  
 terminology, **23-15**  
 explosions, **23-11**  
 apparatus for collecting explosion data, **23-12**  
 boiling-liquid expanding-vapor explosions, **23-13** to **23-14**  
 characterizing explosive behavior for vapors and dusts, **23-12**  
 confined explosions, **23-11**  
 deflagration index, **23-13**  
 detonation and deflagration, **23-11**  
 vapor cloud explosions, **23-13**  
 fire triangle, **23-7**  
 flammability limits in pure oxygen, **23-11**  
 ignition sensitivity of dusts as a function of protective measures, **23-17**  
 relation between flammability properties, **23-8**  
 static electricity, **23-22**  
 brush discharges, **23-23**  
 causes of hazardous discharges with liquids, **23-24**  
 charge dissipation, **23-23**  
 charge induction, **23-22**  
 charge-dissipative materials, **23-23**  
 contact electrification, **23-22**

- hazardous materials and conditions, flammability, static electricity (*Cont.*):  
 corona, 23-23  
 electrostatic charging, 23-22  
 electrostatic discharges, 23-23  
 external causes of incendive static discharges, 23-24  
 mists, 23-22  
 personnel and clothing, 23-24  
 powders, 23-24  
 propagating brush discharges, 23-23  
 spark discharges, 23-23  
 spray nozzles, 23-22  
 terminology, static electricity, 23-22
- hazardous materials and conditions, toxicity:  
 data compilation, 23-32  
 dosage equation, 23-31  
 guidance for the corrosivity of chemical substances, 23-32  
 inert hazards, 23-36  
 asphyxiation and toxicity hazards, 23-36  
 chemical incompatibility hazards, 23-37  
 OSHA's respiratory protection standard, 23-36  
 physiological effects of reduced carbon dioxide atmospheres, 23-37  
 physiological effects of reduced oxygen atmospheres, 23-36  
 sources of inerts, 23-36  
 ingestion toxicity, 23-32  
 inhalation toxicity, 23-31  
 Haber equation, 23-31  
 overinerting, 23-38  
 physical hazards, 23-37  
 high and low pressure, 23-37  
 high and low temperature, 23-37  
 static electricity, 23-22, 23-37  
 probit equation, 23-31  
 safeguards against toxicity hazards, 23-34  
 skin-contact toxicity, 23-32  
 vacuum hazards, 23-34  
 causes of equipment underpressurization, 23-34  
 consequences of vacuum damage, 23-34  
 equipment limitations, 23-34  
 protective measures for equipment, 23-34
- hazardous waste storage and containers, 22-90
- head devices, level measurement, 8-61
- heat capacity, 7-7, 2-489 to 2-498  
 gases, 2-489  
 Benson method, 2-490  
 calculation methods, 2-489  
 ideal gas, 2-490  
 ideal gas heat capacity group contributions, 2-491 to 2-495  
 statistical mechanics, 2-490
- liquids, 2-490  
 calculation methods, 2-495  
 liquid heat capacity group parameters, 2-496 to 2-497  
 Ruzicka-Domalski method, 2-495
- solids, 2-495  
 calculation methods, 2-495  
 Element contributions for modified Kopp's rule, 2-498  
 Goodman method, 2-495  
 group values and nonlinear correction, 2-498  
 modified Kopp's rule, 2-497  
 terms for Goodman method, 2-498
- heat exchangers:  
 air cooled heat exchangers, 11-49 to 11-53  
 air flow control, 11-52  
 heat exchangers, air cooled heat exchangers (*Cont.*):  
 costs, 11-53  
 design considerations, 11-53  
 fan drivers, 11-51  
 fans, 11-51  
 humidification chambers, 11-52  
 trim coolers, 11-52  
 compact and nontubular heat exchangers, 11-55 to 11-60  
 atmospheric sections, 11-60  
 bayonet-tube exchangers, 11-59  
 cascade coolers, 11-59  
 graphite heat exchangers, 11-59  
 plate and frame exchangers, 11-55, 11-58  
 printed-circuit heat exchangers, 11-58  
 spiral tube exchangers, 11-59  
 control, 8-40  
 hairpin/double-pipe, 11-48 to 11-49  
 applications, 11-49  
 construction, principles of, 11-48  
 finned double pipes, 11-48  
 multitube hairpins, 11-48  
 nonmetallic heat exchangers, 11-60  
 ceramic, 11-60  
 PDYF, 11-60  
 Teflon, 11-60  
 solids, heat exchangers for, 11-60 to 11-69  
 divided solids, heat-transfer equipment for, 11-64 to 11-69  
 fusion of solids, equipment for, 11-63  
 sheeted solids, heat-transfer equipment for, 11-63  
 solidification, equipment for, 11-60 to 11-63  
 TEMA-style shell-and-tube, 11-33 to 11-46  
 baffles and tube bundles, 11-43  
 bimetallic tubes, 11-45  
 characteristics of tubing, table, 11-12  
 clad tube sheets, 11-46  
 construction, principle types of, 11-36  
 corrosion in, 11-45  
 costs of, 11-46  
 design considerations, 11-35  
 fabrication, 11-46  
 falling film, 11-40  
 features of, table, 11-11  
 fixed tube sheet, 11-36  
 impervious graphite, 11-46  
 internal floating head, 11-40  
 material of construction, 11-45  
 nonmetallic construction, 11-46  
 outside-packed floating-head, 11-40  
 packed lantern ring, 11-39  
 pull-through floating-head, 11-40  
 shell side, construction of, 11-43  
 tube side, construction of, 11-41  
 U-tube, 11-37  
 heat flow controller, 8-41  
 heat of formation, 7-6  
 heat of reaction, 7-6  
 heat pump, 13-66 to 13-67  
 heats and free energies of formation, inorganic compounds, 2-186 to 2-195  
 heats of combustion, inorganic and organic compounds, 2-196 to 2-200  
 heats of solution:  
 inorganic compounds in water, 2-203 to 2-205  
 organic compounds in water (at infinite dilution and room temperature), 2-206  
 heat-transfer coefficient, 12-6, 12-53, 12-57, 12-76, 12-88  
 heat-transfer rate, 8-41  
 heat-transfer resistances, chemical kinetics, 7-22  
 heat-transfer surface fouling, 8-44  
 helium, thermodynamic properties, 2-272 to 2-273  
 Henry's Law:  
 constants:  
 estimation of, 22-49  
 references, 22-48  
 heptane:  
 activity coefficient plot, 13-14  
 K-value versus residue, 13-12  
 residue map, 13-70  
 thermodynamic properties, 2-274 to 2-275  
 HETP, 16-44  
 height equivalent to a theoretical plate, 13-44 to 13-45  
 hexane:  
 activity coefficient plot, 13-14  
 Antoine vapor pressure, 13-14  
 BIP data, 13-13  
 K-value versus pressure, 13-12  
 residue map, 13-70  
 thermodynamic properties, 2-276 to 2-277  
 Higgins contractor, 16-68  
 high-frequency process disturbances, 8-66  
 high-level computer language, 8-72  
 high/low alarms, 8-67  
 high-order lag, 8-11  
 high-viscosity process valve, 8-76  
 homogeneous catalysis, 7-15  
 homopolymerization, 7-29, 7-30  
 low conversion, 7-30  
 mechanics and kinetics, 7-30  
 step growth, 7-30  
 h-transformation, 16-45  
 HTU, 5-61  
 Huckel, 7-38  
 humid enthalpy, 12-5  
 humid gas density, 12-4, 12-5  
 humid heat, 12-5, 12-6  
 humid volume, 12-5  
 humidity, percentage absolute, 12-4  
 humidity measurement, 12-16 to 12-17  
 dew point method, 12-16  
 electric hygrometer, 12-16  
 gravimetric method, 12-17  
 mechanical hygrometer, 12-17  
 sling or whirling psychrometer, 12-16  
 wet-bulb method, 12-16  
 hydraulic transients, 6-44 to 6-46  
 cavitation, 6-45 to 6-46  
 pulsating flow, 6-45  
 water hammer, 6-44 to 6-45  
 hydrazine, saturated, thermodynamic properties, 2-278  
 hydrocyclone flow patterns, 15-102  
 hydrogen, para. *See* para-hydrogen  
 hydrogen, thermodynamic properties, 2-279 to 2-280  
 hydrogen bromide synthesis, 7-15  
 hydrogen chloride, aqueous, partial pressures, 2-80  
 hydrogen peroxide, thermodynamic properties, 2-282  
 hydrogen sulfide, thermodynamic properties, 2-283 to 2-284  
 hydrometallurgical PFD example, 15-10  
 hygroscopic material, 12-26

gross margin, 9-6  
income before extraordinary loss, 9-6  
income taxes, 9-6  
interest income, 9-6  
net income, 9-6  
net sales, 9-6  
operating income, 9-6
- incompressible flow in pipes and channels, 6-9 to 6-15  
drag reduction, 6-14  
economic pipe diameter:  
laminar flow, 6-15  
turbulent flow, 6-14 to 6-15  
entrance and exit effects, 6-11  
friction factor and Reynolds number, 6-10  
laminar and turbulent flow, 6-10 to 6-11  
mechanical energy balance, 6-9  
molecular flow, 6-15  
noncircular channels, 6-12  
nonisothermal flow, 6-12 to 6-13  
non-Newtonian flow, 6-13 to 6-14  
open channel flow, 6-13  
residence time distribution, 6-11 to 6-12  
slip flow, 6-15 to 6-16  
surface roughness values, 6-10  
vacuum flow, 6-15  
velocity profiles, 6-11
- indirect-fired combustion equipment, 24-41 to 24-42  
coil design:  
arbor, 24-41  
cross-tube convection, 24-41, 24-42  
horizontal-tube box with side-mounted convection tube bank, 24-42  
horizontal-tube cabin, 24-41, 24-42
- indirect-fired combustion equipment, coil  
design (*Cont.*):  
simple vertical, cylindrical, 24-41  
vertical cylindrical helical, 24-42  
vertical-tube, single-row, double-fired heater, 24-41  
function:  
column reboilers, 24-41  
fired reactors, 24-41  
fractionator-feed preheater, 24-41  
heat-transfer fluid, 24-41  
reactor-feed stream, 24-41  
viscous-liquid, 24-41  
inequality constraints, 8-31, 8-33  
inert purge, 16-52  
infinite series:  
convergence and divergence tests, 3-26  
definitions, 3-25  
operations, 3-25 to 3-26  
partial sums, 3-27  
series summation and identities, 3-26 to 3-27  
arithmetic progression, 3-26  
binomial series, 3-26  
exponential series, 3-26  
geometric progression, 3-26  
harmonic progression, 3-26  
logarithmic series, 3-26  
Maclaurin's series, 3-26  
sums for numbers to integer powers, 3-26  
Taylor's series, 3-26  
trigonometric series, 3-26 to 3-27
- information technology, 8-69  
infrared analyzers, 8-62  
in-line blending system, control of, 8-26  
input conversion network, 8-84  
intangibles, economic, 9-5  
goodwill, 9-5, 9-6  
intellectual capital, 9-5  
licenses, 9-5  
particular scrubber, 17-36  
patents, 9-5, 9-6
- integral calculus:  
definite integral, 3-24 to 3-25  
methods of integration, 3-24 to 3-25  
properties, 3-24  
indefinite integral, 3-22 to 3-23  
methods of integration, 3-23  
algebraic substitution, 3-23  
direct formula, 3-23  
partial fractions, 3-23 to 3-24  
series expansion, 3-24  
trigonometric substitution, 3-23
- integral control, 8-14  
integral equations, 3-36 to 3-37  
classification, 3-36  
methods of solution, 3-37  
numerical solution, 3-54  
relation to differential equations, 3-36 to 3-37
- integral transforms, 3-37 to 3-40  
convolution integral, 3-39  
Fourier cosine transform, 3-39 to 3-40  
Fourier transform, 3-39  
Laplace transform, 3-37 to 3-40  
z-transform, 3-39
- integrated absolute error, control, 8-16  
intelligent alarm, use in control, 8-68  
intelligent field devices, use in control, 8-69  
interaction number, 17-22  
interest, 9-23  
effective rates, 9-25  
types of, 9-23  
compounding-discounting, 9-23  
continuous compounding, 9-23  
discrete compounding, 9-23  
simple, 9-23
- interfacial mass-transfer rates, 14-89  
approach to equilibrium-finite contactor with no bypassing, 14-89  
bypassing, 14-90  
transfer coefficient-impact of droplet size, 14-90  
turbulence, effect of, 14-90
- interlocks, 8-49  
intermodal communications, 8-70  
internal diffusion, 12-26  
internal energy:  
function of T and P or T and y, 4-6 to 4-7  
postulate definition, 4-4
- interpolation and finite differences, 3-45 to 3-47  
central differences, 3-46  
divided differences of higher order, 3-45  
equally spaced backward differences, 3-46  
equally spaced forward differences, 3-45  
Lagrange interpolation formulas, 3-46  
linear interpolation, 3-45  
spline functions, 3-46 to 3-47
- intraparticle diffusion, 7-20  
effectiveness factor, 7-20  
external mass-transfer resistance, 7-22  
gas diffusivity, 7-20  
observed order and activation energy, 7-20  
reaction networks, 7-21  
reaction rate, 7-20
- intraparticle transport mechanisms, 16-18  
inventory evaluation and cost control, 9-9  
inverse trigonometric functions, 3-17  
investment capital, 9-10  
ion electrodes, 8-63  
ion exchange:  
Asahi countercurrent process, 16-69  
Himsley continuous system, 16-69  
mixed-bed, 16-54  
regeneration, 16-54
- ion exchangers:  
fixed bed, design data, 16-68  
physical properties, 16-9 to 16-11  
pore size classification, 16-8
- ionic self-diffusivities, 16-20  
irreversible reaction, 7-5  
ISA symbols, 8-40  
isobutane, thermodynamic properties, 2-286 to 2-287  
isobutene, thermodynamic properties, 2-288 to 2-289  
isolation, 8-78  
isosteric heat of adsorption, 16-12  
isotachic pattern, 16-39
- isotherms:  
BET, 16-13  
constant pattern behavior, 16-34  
constant separation factor, 16-35  
Freundlich, 16-13  
linear, 16-13  
Sips, 6-13  
square-root spreading, 16-37  
Toth, 16-13
- jet behavior, 6-20 to 6-22  
Joule-Thomson effect:  
approximate inversion-curve locus in reduced coordinates, 2-137  
Joule-Thomson coefficient, additional references, 2-137
- Kachford and Kile, 13-5  
Karr column, 15-84  
kinetic control, electrochemical reactions, 7-32  
kinetic models, simplified, 12-32  
experimental methods, 12-35 to 12-36  
moisture determination, 12-36  
sample techniques, 12-36

- kinetic parameters, 7-35  
 Arrhenius temperature dependence, 7-35  
 kinetic rate equation, complex, 7-37  
 kinetics, surface-reaction controlling, 7-17  
 Kirchhoff's law, 5-19  
 Kister and Gill correlation, structured packing, 14-59

 effect of physical properties on drop size, 14-93  
 effect of pressure drop and nozzle size, 14-93  
 entrainment due to gas bubbling/jetting through a liquid, 14-96  
 fog condensation-the-other way to make little droplets, 14-97  
 growth on foreign nuclei, 14-98  
 hydraulic (pressure) nozzles, 14-93  
 isolated droplet breakup-in a velocity field, 14-92  
 liquid breakup into droplets, 14-91  
 liquid-column breakup, 14-92  
 liquid-sheet breakup, 14-92  
 pipeline contactors, 14-95  
 rotary atomizers, 14-95  
 spontaneous (homogeneous) nucleation, 14-98  
 spray angle, 14-93  
 two-fluid (pneumatic) atomizers, 14-94  
 "upper limit" flooding vertical tubes, 14-97  
 liquid/liquid equilibrium, thermodynamics, 4-35  
 liquid-liquid extraction, 15-6 to 15-22  
 definitions:  
 continuous phase, 15-10  
 counter-current cascade, 15-11  
 counter-current extraction, 15-11  
 cross-current extraction, 15-11  
 cross-flow extraction, 15-11  
 differential contactor, 15-11  
 dilutant, 15-10  
 dispersed phase, 15-10  
 liquid-liquid extraction, definitions (*Cont.*):  
 dispersion, 15-10  
 distribution coefficient (k), 15-10  
 distribution constant (k), 15-10  
 distribution ratio, 15-11  
 emulsion, 15-10  
 equilibrium stage, 15-10  
 extract, 15-10  
 extractant, 15-10  
 extraction factor, 15-11  
 extraction solvent, 15-10  
 feed, 15-10  
 feed as carrier solvent, 15-10  
 flood point, 15-11  
 flooding, 15-11  
 fractional extraction, 15-11  
 interfacial tension, 15-10  
 k-value, 15-10  
 liquid-liquid extraction, 15-10  
 mass-transfer coefficients, 15-11  
 mass-transfer units, 15-11  
 mixed solvent as solvent blend, 15-10  
 modifier, 15-10  
 $pK_{15}$ , 15-15  
 partition ratio (k), 15-10  
 phase inversion, 15-11  
 phase velocity, 15-11  
 raffinate, 15-10  
 Sauter-mean drop diameter, 15-10  
 selectivity, 15-11  
 separating agent, 15-10  
 separation factor, 15-11  
 solutes, 15-10  
 solutrope, 15-11  
 solvent extraction, 15-10  
 staged contactor, 15-11  
 standard extraction, 15-11  
 theoretical stage, 15-10  
 throughput, 15-11  
 uses, 15-7 to 15-10  
 acetic acid recovery example, 15-8  
 antibiotic recovery from fermentation broth, 15-8  
 aromatic compound petrochemical separation, 15-8  
 distillation impracticalities, 15-8  
 hydro metallurgical applications, 15-8  
 removal of acid residue from liquefied petroleum gases (LPG), 15-8  
 liquid-liquid extraction, equipment, 15-58 to 15-93  
 agitated extraction columns, 15-79 to 15-86  
 kuhni column, 15-82 to 15-83  
 pulsed-liquid columns, 15-85  
 raining-bucket contactor, 15-85 to 15-86  
 reciprocating-plate columns, 15-83 to 15-84  
 rotating-disk contactor, 15-84 to 15-85  
 rotating-impeller columns, 15-79 to 15-80  
 scheibel extraction column, 15-80 to 15-82  
 centrifugal extractors, 15-92 to 15-93  
 multistage, 15-92 to 15-93  
 single-stage, 15-91 to 15-92  
 extractor selection, 15-58 to 15-59  
 volumetric efficiency, 15-59  
 hydrodynamics of column extractors, 15-59 to 15-63  
 axial mixing, 15-60 to 15-62  
 computational fluid dynamics (CFD), 15-62 to 15-63  
 flooding phenomena, 15-59 to 15-60  
 mixer-settler equipment, 15-86 to 15-91  
 liquid-liquid mixes design, 15-87 to 15-88  
 mass-transfer models, 15-86 to 15-87  
 miniplant tests, 15-87  
 scale-up, 15-88 to 15-89

- liquid-liquid extraction, equipment, mixer-settler equipment (*Cont.*):  
 specialized equipment, 15-89 to 15-90  
 suspended-fiber contactor, 15-90 to 15-91  
 static extraction columns, 15-63 to 15-79  
 baffle tray columns, 15-78 to 15-79  
 features and design concepts, 15-63 to 15-69  
 packed columns, 15-70 to 15-74  
 sieve tray columns, 15-74 to 15-78  
 spray columns, 15-69 to 15-70
- liquid-liquid extraction, thermodynamic basis, 15-22 to 15-32  
 activity coefficients, 15-22 to 15-25  
 extraction factor, 15-22 to 15-23  
 ionizable organic salts and pH, 15-23 to 15-25  
 min and max solvent-to solvent ratios, 15-23  
 salting-out, salting-in and non-ionic solutes, 15-24  
 separation factor, 15-23  
 temperature effect, 15-23 to 15-24
- data collection equations, 15-27 to 15-32  
 data quality, 15-28 to 15-32  
 thermodynamic models, 15-28  
 tie-line correlations, 15-27 to 15-28
- experimental methods, 15-27  
 phase diagrams, 15-25 to 15-27  
 plait point, 15-26  
 phase equilibrium data source, 15-32  
 recommended model systems, 15-32
- liquid-liquid phase separation equipment, 15-96 to 15-103  
 feed characteristics, 15-96  
 other separators, 15-101 to 15-102  
 centrifuges, 15-101  
 coalescers, 15-101  
 electrotreaters, 15-102  
 hydrocyclones, 15-101 to 15-102  
 ultrafiltration membranes, 15-102  
 overall process considerations, 15-96  
 settlers, 15-97 to 15-100  
 decanters with coalescing intervals, 15-99  
 design considerations, 15-97 to 15-98  
 sizing methods, 15-99 to 15-100  
 vented decanters, 15-98 to 15-99
- liquid-liquid reactors, 19-41 to 19-42  
 examples, 19-43  
 types of, 19-42 to 19-47  
 agitated stir tanks, 19-42 to 19-44  
 bubble columns, 19-44 to 19-46  
 packed, spray and trayed towers, 19-46 to 19-47  
 tubular reactors, 19-46
- liquids, storage of, 10-140  
 atmospheric tanks, 10-140  
 types of, 10-143  
 pressure tanks:  
 calculation of tank volume, 10-144  
 container materials and safety, 10-145  
 pond and underground cavern storage, 10-146  
 shop-fabricated storage tanks, 10-140  
 USTs versus ASTs, 10-140  
 aboveground storage tank types and options, 10-142  
 double-wall, 10-142  
 elevated tanks, 10-143  
 environmental regulations, 10-142  
 fire codes, 10-141  
 fixed roofs, 10-143  
 open tanks, 10-143  
 posttensioned concrete, 10-143  
 secondary containment ASTs, 10-142  
 separation distances, 10-144  
 standards, 10-141  
 state and local jurisdictions, 10-142  
 variable-volume tanks, 10-143  
 venting, 10-144
- lithium, saturated, thermodynamic properties, 2-292
- load cells, serial interface, 8-66  
 loading ratio correlation, 16-13  
 local equilibrium theory, 16-31  
 Loeb equation, 17-56  
 logical operators, 8-71  
 long-term scheduling, 8-48  
 low alarms, 8-67  
 low level, switch, 8-50  
 low-frequency process disturbances, 8-66  
 lumping, mechanism reduction, 7-38, 7-39  
 magnetic flowmeters, 8-59 to 8-60  
 magnetically coupled devices, 8-60  
 management information systems, 8-69  
 manufacturing expenses, 9-18 to 9-21  
 manufacturing resource planning, 8-68  
 mass action law, 16-14 to 16-17  
 mass flow controllers, 8-60  
 mass flow network, 7-30  
 mass fraction, 12-4  
 mass ratio, 12-4  
 mass spectroscopy, 8-63  
 mass transfer, 5-43 to 5-83  
 Chilton-Colburn analogy, 5-83  
 coefficients, 5-45, 5-61  
 definitions, 5-61  
 effects of chemical reactions, 5-74, 5-82 to 5-83  
 effects of concentrations, 5-74  
 effects of system physical properties, 5-74, 5-82  
 effects of total pressure, 5-68  
 effects of total temperature, 5-68  
 flow in pipes, 5-66 to 5-68  
 packed two-phase contactors, 5-80 to 5-82  
 particles, drops, and bubbles in agitated systems, 5-75 to 5-76  
 single flat plate, 5-63 to 5-64  
 submerged objects, 5-69 to 5-70  
 volumetric, 5-83  
 constant separation factors, 16-27 to 16-28, 16-30  
 correlations, 5-62 to 5-82  
 drops, bubbles, and bubble columns, 5-75 to 5-76  
 falling films, 5-65  
 fixed and fluidized beds, 5-77 to 5-79  
 external mass-transfer control, 16-27  
 interfacial mass transfer area, 5-83  
 principles, 5-59 to 5-61  
 concentrated systems, 5-60 to 5-61  
 diluted systems, 5-59 to 5-60  
 rate equations in absorbent particles, 16-24  
 solid diffusion control, 16-27  
 theories, 5-61 to 5-62
- mass-transfer coefficients, 12-6, 12-53, 14-24  
 mass-transfer controlled, 7-33  
 material balance, 5-49, 16-17  
 materials:  
 low temperature metals, 25-45 to 25-46  
 high-temperature metals, 25-46 to 25-51  
 materials of construction, properties:  
 aluminum and alloys, 25-33  
 brass, 25-34  
 bronze, 25-34  
 cast iron:  
 austenitic, 25-5, 25-31  
 carbon steel, 25-6  
 duplex, 25-32  
 low-alloy, 25-6  
 martensitic alloys, 25-31  
 6Mo family alloys, 25-32  
 stainless steel, ferritic, 25-31  
 ceramic-fiber insulated linings, 25-51
- materials of construction, properties (*Cont.*):  
 copper and alloys, 25-34  
 creep, 25-47  
 cupronickel, 25-34  
 firebrick, 25-49  
 Hastelloy alloys, 25-33  
 incoloy, 25-35  
 inorganic, nonmetallics:  
 brick, 25-36  
 cement, concrete, 25-37  
 glass, 25-36  
 glassed steel, 25-36  
 porcelain, 25-36  
 lead and alloys, 25-34  
 Monel 400, 25-33  
 nickel alloys, 25-32 to 25-34  
 organic, nonmetallics, 25-37 to 25-44  
 epoxy, 25-44  
 ethylene chlorotrifluoroethylene, 25-41  
 ethylene trifluoroethylene, 25-41  
 fluorinated ethylene propylene, 25-37  
 furon, 25-44  
 perfluoroalkoxy, 25-37  
 polyethylene, 25-41  
 polytetrafluoroethylene, 25-37  
 polyvinyl chloride, 25-41  
 polyvinylidene fluoride, 25-37  
 rubber, 25-44  
 thermoplastics, 25-41  
 thermosets, 25-37  
 stress rupture, 25-47  
 tantalum, 25-34  
 tinplate, 25-41  
 titanium, 25-34  
 zirconium, 25-34
- mathematical constants, 3-4  
 mathematical signs, 3-4  
 matrix algebra, 3-40 to 3-41  
 equality of matrices, 3-40  
 matrices, 3-40  
 matrix operations, 3-40 to 3-41  
 matrix calculus, 3-41  
 differentiation, 3-41  
 integration, 3-41  
 matrix computations, 3-41 to 3-43  
 LU factorization, 3-41 to 3-42  
 principal component analysis, 3-42 to 3-43  
 QR factorization, 3-42  
 singular-value decomposition, 3-42  
 McCabe-Thiele method, 13-16 to 13-25  
 construction, 13-19 to 13-22  
 B-line, 13-19 to 13-22  
 feed stage location, 13-22  
 operating line, 13-19 to 13-22  
 optimum reflux ratio, 13-24  
 pinch point, 13-24  
 MCM-41, 16-8  
 measurement, direct mass, 8-61  
 mechanical centrifugal separators, 17-36  
 mechanical deactivation, 7-23  
 mechanical scrubbers, 17-43  
 melt crystallization:  
 comparison of features, 20-3  
 comparison of processes, 20-3  
 from the bulk, 20-6 to 2-10  
 axial dispersion coefficients, 20-8  
 center-fed crystallizers, 20-7 to 20-9  
 end-fed crystallizers, 20-9  
 equipment and applications, 20-9 to 20-10  
 phase diagrams, 20-3, 20-4  
 melting point, normal, 2-471 to 2-472  
 calculation methods, 2-471  
 Constantinov and Gani method, 2-471  
 first-order groups contributions, 2-472  
 second-order groups contributions, 2-472

## 20 INDEX

- membrane separation processes:
    - background and definitions:
      - applications, **20-36 to 20-37**
      - component transport, **20-38 to 20-39**
      - membrane types, **20-37 to 20-38**
    - membrane systems, modules:
      - NFF, **20-40 to 20-41**
      - process configurations:
        - batch and fed-batch, **20-43 to 20-45**
        - continuous, **20-44 to 20-45**
        - diafiltration, **20-43 to 20-44**
        - single-pass, **20-42, 20-44**
      - TFF, **20-40 to 20-43**
      - commercial modules, **20-43**
    - membranes, gas separation:
      - description, **20-57**
      - economics, **20-61 to 20-63**
        - compression, **20-61**
        - membrane replacement, **20-63**
        - product losses, **20-62**
      - examples:
        - carbon dioxide-methane, **20-57**
        - gas dehydration, **20-58**
        - helium, **20-58**
        - hydrogen, **20-57**
        - oxygen-nitrogen, **20-57**
        - vapor recovery, **20-58**
      - kinetic diameters, **20-57**
      - principles of operation:
        - Barrer conversion factors, **20-58**
        - driving force, **20-58**
        - equations, **20-58**
        - gas permeation units, **20-58**
        - limiting cases, **20-59**
        - plasticization, **20-59**
      - selectivity and permeability, **20-59 to 20-60**
        - high performance polymers, **20-59**
        - polarization, **20-60**
        - temperature effects, **20-60**
        - time effects, **20-60**
      - system design, **20-60 to 20-61**
        - energy requirements, **20-61**
        - fouling, **20-61**
        - modules and housings, **20-61**
        - partial pressure pinch, **20-61**
      - types of:
        - advanced materials, **20-60**
        - catalytic, **20-60**
        - caulked, **20-60**
        - metallic, **20-60**
        - organic, **20-60**
    - membranes, liquid separation:
      - description, **20-57**
      - economics, **20-61 to 20-63**
        - compression, **20-61**
        - membrane replacement, **20-63**
        - product losses, **20-62**
      - examples:
        - carbon dioxide-methane, **20-57**
        - gas dehydration, **20-58**
        - helium, **20-58**
        - hydrogen, **20-57**
        - oxygen-nitrogen, **20-57**
        - vapor recovery, **20-58**
      - kinetic diameters, **20-57**
      - principles of operation:
        - Barrer conversion factors, **20-58**
        - driving force, **20-58**
        - equations, **20-58**
        - gas permeation units, **20-58**
        - limiting cases, **20-59**
        - plasticization, **20-59**
      - selectivity and permeability, **20-59 to 20-60**
        - high performance polymers, **20-59**
        - polarization, **20-60**
        - temperature effects, **20-60**
        - time effects, **20-60**
      - system design, **20-60 to 20-61**
        - energy requirements, **20-61**
        - fouling, **20-61**
        - modules and housings, **20-61**
        - partial pressure pinch, **20-61**
      - types of:
        - advanced materials, **20-60**
        - catalytic, **20-60**
        - caulked, **20-60**
        - metallic, **20-60**
        - organic, **20-60**
    - membranes, vapor separation:
      - description, **20-57**
      - economics, **20-61 to 20-63**
        - compression, **20-61**
        - membrane replacement, **20-63**
        - product losses, **20-62**
      - examples:
        - carbon dioxide-methane, **20-57**
        - gas dehydration, **20-58**
        - helium, **20-58**
        - hydrogen, **20-57**
        - oxygen-nitrogen, **20-57**
        - vapor recovery, **20-58**
      - kinetic diameters, **20-57**
      - principles of operation:
        - Barrer conversion factors, **20-58**
        - driving force, **20-58**
        - equations, **20-58**
        - gas permeation units, **20-58**
        - limiting cases, **20-59**
        - plasticization, **20-59**
      - selectivity and permeability, **20-59 to 20-60**
        - high performance polymers, **20-59**
        - polarization, **20-60**
        - temperature effects, **20-60**
        - time effects, **20-60**
      - system design, **20-60 to 20-61**
        - energy requirements, **20-61**
        - fouling, **20-61**
        - modules and housings, **20-61**
        - partial pressure pinch, **20-61**
      - types of:
        - advanced materials, **20-60**
        - catalytic, **20-60**
        - caulked, **20-60**
        - metallic, **20-60**
        - organic, **20-60**
  - membrane systems, modules:
    - NFF, **20-40 to 20-41**
    - process configurations:
      - batch and fed-batch, **20-43 to 20-45**
      - continuous, **20-44 to 20-45**
      - diafiltration, **20-43 to 20-44**
      - single-pass, **20-42, 20-44**
    - TFF, **20-40 to 20-43**
    - commercial modules, **20-43**
  - membranes, gas separation:
    - description, **20-57**
    - economics, **20-61 to 20-63**
      - compression, **20-61**
      - membrane replacement, **20-63**
      - product losses, **20-62**
    - examples:
      - carbon dioxide-methane, **20-57**
      - gas dehydration, **20-58**
      - helium, **20-58**
      - hydrogen, **20-57**
      - oxygen-nitrogen, **20-57**
      - vapor recovery, **20-58**
    - kinetic diameters, **20-57**
    - principles of operation:
      - Barrer conversion factors, **20-58**
      - driving force, **20-58**
      - equations, **20-58**
      - gas permeation units, **20-58**
      - limiting cases, **20-59**
      - plasticization, **20-59**
    - selectivity and permeability, **20-59 to 20-60**
      - high performance polymers, **20-59**
      - polarization, **20-60**
      - temperature effects, **20-60**
      - time effects, **20-60**
    - system design, **20-60 to 20-61**
      - energy requirements, **20-61**
      - fouling, **20-61**
      - modules and housings, **20-61**
      - partial pressure pinch, **20-61**
    - types of:
      - advanced materials, **20-60**
      - catalytic, **20-60**
      - caulked, **20-60**
      - metallic, **20-60**
      - organic, **20-60**
  - membranes, liquid separation:
    - description, **20-57**
    - economics, **20-61 to 20-63**
      - compression, **20-61**
      - membrane replacement, **20-63**
      - product losses, **20-62**
    - examples:
      - carbon dioxide-methane, **20-57**
      - gas dehydration, **20-58**
      - helium, **20-58**
      - hydrogen, **20-57**
      - oxygen-nitrogen, **20-57**
      - vapor recovery, **20-58**
    - kinetic diameters, **20-57**
    - principles of operation:
      - Barrer conversion factors, **20-58**
      - driving force, **20-58**
      - equations, **20-58**
      - gas permeation units, **20-58**
      - limiting cases, **20-59**
      - plasticization, **20-59**
    - selectivity and permeability, **20-59 to 20-60**
      - high performance polymers, **20-59**
      - polarization, **20-60**
      - temperature effects, **20-60**
      - time effects, **20-60**
    - system design, **20-60 to 20-61**
      - energy requirements, **20-61**
      - fouling, **20-61**
      - modules and housings, **20-61**
      - partial pressure pinch, **20-61**
    - types of:
      - advanced materials, **20-60**
      - catalytic, **20-60**
      - caulked, **20-60**
      - metallic, **20-60**
      - organic, **20-60**
  - membranes, vapor separation:
    - description, **20-57**
    - economics, **20-61 to 20-63**
      - compression, **20-61**
      - membrane replacement, **20-63**
      - product losses, **20-62**
    - examples:
      - carbon dioxide-methane, **20-57**
      - gas dehydration, **20-58**
      - helium, **20-58**
      - hydrogen, **20-57**
      - oxygen-nitrogen, **20-57**
      - vapor recovery, **20-58**
    - kinetic diameters, **20-57**
    - principles of operation:
      - Barrer conversion factors, **20-58**
      - driving force, **20-58**
      - equations, **20-58**
      - gas permeation units, **20-58**
      - limiting cases, **20-59**
      - plasticization, **20-59**
    - selectivity and permeability, **20-59 to 20-60**
      - high performance polymers, **20-59**
      - polarization, **20-60**
      - temperature effects, **20-60**
      - time effects, **20-60**
    - system design, **20-60 to 20-61**
      - energy requirements, **20-61**
      - fouling, **20-61**
      - modules and housings, **20-61**
      - partial pressure pinch, **20-61**
    - types of:
      - advanced materials, **20-60**
      - catalytic, **20-60**
      - caulked, **20-60**
      - metallic, **20-60**
      - organic, **20-60**
- methane (*Cont.*):
  - K*-value versus pressure, **13-12**
  - pressure versus time data obtained from gas explosion apparatus, **23-12**
  - thermodynamic properties, **2-296 to 2-297**
- methane in air, pressure as a function of volume percent concentration, **23-12**
- methanol:
  - Antoine vapor pressure, **13-14**
  - BIP data, **13-13**
  - residue curve, **13-90**
  - residue map, **13-79**
  - thermodynamic properties, **2-298 to 2-299**
- methyl acetate:
  - Antoine vapor pressure, **13-14**
  - BIP data, **13-13**
- methyl butane (isopentane), thermodynamic properties, **2-300 to 2-301**
- methyl chloride, saturated, thermodynamic properties, **2-304**
- methyl ethyl ketone:
  - residue map, **13-70, 13-79**
  - sensitivity of composition and temperature, **13-79 to 13-80**
- methyl pentane (isohexane), thermodynamic properties, **2-302 to 2-303**
- microfiltration:
  - applications, **20-56 to 20-57**
    - chemical, **2-57**
    - flow schemes, **20-57**
    - food and dairy, **20-57**
    - pharmaceutical, **20-56**
    - water, **20-57**
  - description, **20-54**
  - economics, **20-57**
  - equipment configuration:
    - cassettes, **20-56**
    - ceramics, **20-56**
    - conventional design, **20-56**
  - examples, **20-54**
  - membranes, **20-54 to 20-56**
    - ceramic, **20-54**
    - characterization and tests, **20-55 to 2-56**
    - from solids, **20-54**
    - inversion, **20-55**
    - stretched polymers, **20-55**
    - track-etched, **20-54**
  - process limitations:
    - fouling, **20-56**
    - polarization, **20-56**
  - microprocessor-based transmitters, **8-66**
  - microscopic reversibility, **7-7**
- mixed potential principle, **7-33**
- mixed-feed evaporator, control of, **8-45**
- mixers-settlers, **15-89**
  - equipment, **18-21**
    - flow, line mixers, **18-21**
      - definition, **18-21**
      - injectors, **18-21**
      - jet mixers, **18-21**
      - line mixer, **18-22**
      - nozzles, **18-21**
      - orifices, **18-21**
      - packed tubes, **18-22**
      - pipe lines, **18-22**
      - pumps, **18-22**
      - valves, **18-22**
    - liquid-liquid extraction, **18-24**
    - purposes, **18-20**
  - vessels, agitated:
    - coalescence, **18-24**
    - dispersion, **18-23**
    - drop size, **18-23**
    - mechanical agitation, **18-23**
    - uniformity, **18-23**
- mixing:
  - maximum mixedness, **19-18 to 19-20**
  - mixing times, **19-20**
  - ratio, **12-4, 12-6**
- mobile-bed scrubbers, **17-42**
- model development, **8-31**

 operational factors, 20-65  
 vapor feed, 20-65
- petroleum fuels:  
 considerations:  
 commercial, 24-10  
 safety, 24-10  
 properties, 24-8 to 24-10  
 heat capacity, 24-9  
 heat of combustion, 24-9  
 kinematic viscosity, 24-9  
 pour point, 24-9  
 relative density, 24-9  
 thermal conductivity, 24-9 to 24-10  
 thermal expansion, 24-9  
 ultimate analyses, 24-9  
 requirements for fuel oils, 24-8  
 specification, 24-7 to 24-8
- PFBC unit, 17-19
- pH measurement, 8-63
- pH neutralization, 8-26
- phase rule, 4-27
- phase separation, 14-111  
 gas-phase continuous systems, 1-111  
 collection equipment, 14-114  
 collection mechanisms, 14-113  
 continuous phase uncertain, 14-126  
 design and selection of collection devices, 14-113  
 electrically charged collectors, 14-25  
 electrostatic precipitators, 14-125  
 energy requirements for inertial-impaction efficiency, 14-123  
 fiber mist eliminators, 14-125  
 fine mists, collection of, 14-124  
 gas sampling, 14-112  
 mist and spray definitions, 14-112  
 other collectors, 14-126  
 particle growth and nucleation, 14-126  
 particle size analysis, 14-112
- liquid-phase continuous systems, 14-126  
 automatic foam control, 14-129  
 chemical defoaming techniques, 14-128  
 foam prevention, 14-129  
 physical defoaming techniques, 14-128  
 separation of foam, 14-127  
 separations of unstable systems, 14-127  
 types of gas-in-liquid dispersions, 14-126
- pH-auxostat, 7-35
- phosgene synthesis, 7-14
- photobodies, 8-58
- photoconductors, 8-58
- photoelectric pyrometer, 8-58
- photometric moisture analysis, 8-64
- physical properties:  
 prediction and correlation, 2-463 to 2-517  
 density, 2-497 to 2-504  
 flammability properties, 2-515 to 2-517  
 heat capacity, 2-489 to 2-497  
 latent enthalpy, 2-486 to 2-489  
 physical constants, 2-468 to 2-477  
 surface tension, 2-513 to 2-515  
 thermal conductivity, 2-509 to 2-513  
 thermal properties, 2-478 to 2-486  
 vapor pressure, 2-477 to 2-478  
 viscosity, 2-504, 2-509
- physical properties, estimation methods, classification of, 2-467 to 2-468  
 computational chemistry (CCC), 2-468  
 corresponding states (CS), 2-467  
 empirical QSPR correlations, 2-468

- physical properties, estimation methods,  
classification of (*Cont.*):  
group contributions (GC), 2-467 to 2-468  
molecular simulations, 2-468  
theory and empirical extensions, 2-467
- physical properties, pure substances:  
elements and inorganic compounds, 2-7 to 2-27  
organic compounds, 2-28 to 2-46
- physical property specifications, 8-35
- physisorption, 16-4
- PID controllers, 8-5
- piezoelectric crystal, 8-63
- piezoelectric method, 8-63
- piezoelectric transducers, 8-59
- piezoelectric transmitter, 8-61
- piezoresistive transducers, 8-59
- pilot-operated regulator, 8-93
- pipe fittings:  
locations of orifices and nozzles relative to, 10-20  
miter bends, nomenclature for, 10-113
- pipe joining, acceptance criteria for welds and  
examination methods, 10-130 to 10-131
- pipes, properties for, 10-78 to 10-80
- pipng and instrumentation diagram, 8-39
- pipng materials, cost rankings and cost ratios for,  
10-136
- pipng system materials, selection of, 10-74  
bolting, 10-85  
flanged joints, 10-81  
flanged-end fittings, 10-81  
flanged-end pipe, 10-81  
flanges, carbon and alloy steel, types of, 10-82,  
10-86  
ring joint flanges, 10-85  
with conical ends, 10-104
- gates, 10-93  
dimensions of, 10-94 to 10-95  
globe, 10-96  
plug, 10-97, 10-98  
swing check, 10-98  
tilting-disk check valves, 10-98
- general considerations, 10-74
- metallic components, 10-76  
seamless pipe and tubing, 10-76  
tubing, 10-76  
welded pipe and tubing, 10-76
- methods of pipe joining, 10-76  
branch connections, 10-77  
seal weld, 10-81  
socket weld, 10-81  
straight-pipe threads, 10-81  
threaded joints, 10-81  
union joints, 10-81  
welded joints, 10-77
- miscellaneous mechanical joints, 10-87  
bite-type fitting joints, 10-89, 10-90  
compression-fitting joints, 10-89, 10-90  
expanded joints, 10-87  
flared-fitting joint, 10-89  
grooved joints, 10-88  
O-ring seal joints, 10-89, 10-90  
packed-gland joints, 10-87  
poured joints, 10-87  
pressure-seal joints, 10-88, 10-89  
push-on joints, 10-87  
seal ring joints, 10-88  
silver brazed joints, 10-89  
soldered joints, 10-89  
tubing joints, 10-88  
V-clamp joints, 10-88
- pipe, fitting and bends, 10-89  
butt-welding fittings, 10-90, 10-93  
elbow fittings, 10-90  
flanged fittings, dimensions of, 10-91 to  
10-92
- pipng system materials, selection of, pipe, fitting  
and bends (*Cont.*):  
malleable-iron threaded fittings, 10-90  
reducing elbow fittings, 10-93
- pipe, thermoplastic, recommended temperature  
limit for, 10-76  
thermoplastic used as linings,  
thermosetting resin pipe, 10-77
- specific material consideration, metals, 10-75
- specific material consideration, nonmetallics,  
10-75
- valves, 10-93  
angle, 10-96  
ball, 10-97  
butterfly, 10-98  
check and lift-check, 10-98  
diaphragm, 10-96  
dual-plate check, 10-98
- pipng systems, cast iron, ductile iron, and high-sili-  
con iron, 10-98  
cast iron and ductile iron, 10-98  
ductile-iron pipe, dimension of, 10-100  
hard-drawn copper threadless pipe, 10-103  
high-silicon iron, 10-99  
pipe, 10-100
- pipng systems, cost comparison of, 10-135
- pipng systems, design of, 10-107  
air condensation effects, 10-108  
category D, 10-107  
category M, 10-107  
classification of fluid services, 10-107  
cyclic effects, 10-108  
design conditions, 10-107  
ambient influences, 10-107  
dynamic effects, 10-108  
pressure, 10-107  
temperature, 10-107  
thermal expansion and contraction effects,  
10-108  
weight effects, 10-108
- design criteria, metallic pipe, 10-108
- effects of support, anchor, and terminal move-  
ments, 10-108
- limits of calculated stresses due to sustained  
loads and displacement strains, 10-111
- pressure design of metallic components, 10-111
- reactions:  
anchors for expansion joints, 10-123  
displacement strains, 10-123  
elastic behavior, 10-123  
expansion joints, 10-121  
maximum reactions for simple systems,  
10-120  
pipe supports and attachments, 10-124  
support fixtures, 10-123
- reduced ductility, 10-108
- safeguarding, 10-107
- test conditions, 10-113
- thermal expansion and flexibility, 10-114  
cold spring, 10-115  
displacement strains, 10-114  
flexibility stress, 10-115
- pipng systems, flexibility classification for,  
10-121  
required weld quality assurance, 10-120  
requirements for analysis, 10-115  
total displacement strains, 10-114  
values for reactions, 10-115
- pipng systems, fabrication, 10-123  
assembly and erection, 10-126  
bending and forming, 10-126  
joining nonmetallic pipe, 10-126  
preheating and heat treatment, 10-126  
welding, brazing, or soldering, 10-123  
typical weld imperfections, 10-132
- pipng systems, forces of pipng on process  
machinery and pipng vibration, 10-135  
displacement strains, 10-123  
elastic behavior, 10-123  
expansion joints, 10-121  
maximum reactions for complex systems,  
10-121  
maximum reactions for simple systems, 10-120  
pipe supports and attachments, 10-124  
support fixtures, 10-123
- pipng systems, heat tracing of, 10-135  
types of heat-tracing systems, 10-137  
electric tracing, types of, 10-139 to 10-140  
fluid-tracing systems, 10-137  
steam tracing versus electric tracing, economics  
of, 10-137  
steam-tracing system, 10-137
- pipng systems, metallic with nonmetallic pipe and  
linings, 10-103  
cement-lined carbon-steel pipe, 10-103, 10-104  
concrete pipe, 10-104  
fused silica or fused quartz, 10-105  
glass pipe and fittings, 10-104  
dimensions for glass pipe and flanged joints,  
10-104  
glass-lined steel pipe and fittings, 10-105  
plastic pipe, 10-106  
clamped-insert joint, 10-106  
polyethylene, 10-106  
polypropylene, 10-107  
plastic-lined steel pipe, 10-105  
kynar liners, 10-105  
polypropylene liners, 10-105  
polyvinylidene chloride liners, 10-105  
PTFE and PFA lined steel pipe, 10-105  
reinforced-thermosetting-resin (RTR) pipe,  
10-107  
hanger-spacing ranges for RTR pipe, 10-107  
rubber-lined steel pipe, 10-106

   chromium alloys, **2-461**  
   insulating materials at high temperatures, **2-461**  
   insulating materials at low temperatures, **2-462**  
   insulating materials at moderate temperatures, **2-462**  
   liquids, inorganic and organic substances, **2-439 to 2-444**  
   metals, **2-460**  
   organic liquids, **2-450**  
   refrigeration and building insulation materials, **2-330, 2-461**  
   vapor, inorganic and organic substances, **2-433 to 2-438**  
 thermophysical properties, miscellaneous saturated liquids, **2-452 to 2-453**  
 viscosities, inorganic and organic substances:  
   gases, **2-317, 2-446 to 2-447**  
   liquids at 1 atm, **2-427 to 2-432, 2-448 to 2-449**  
   sucrose solutions, **2-450**  
   vapor, **2-241 to 2-426**  
 tray columns, flooding, **14-36**  
   derating ("system") factors, **14-40**  
   downcomer backup flooding, **14-38**  
   downcomer choke flooding, **14-39**  
   entrainment (jet) flooding, **14-36**  
   spray entrainment flooding prediction, **14-36**  
 tray columns, gas-liquid systems, **14-26 to 14-34**  
   baffle trays, **14-34**  
   bubble-cap trays, **14-34**  
   centrifugal force deentrainment, **14-34**  
   clearance under the downcomer, **14-31**  
   downcomers, **14-29**  
   dual flow trays, **14-34**  
   flow regimes on trays, **14-17**  
   fractional hole area, **14-31**  
   hole sozes, **14-31**

## 30 INDEX

- tray columns, gas-liquid systems (*Cont.*):  
  multipass balancing, 14-32  
  outlet weir, 14-29  
  radial trays, 14-34  
  tray area definitions, 14-26  
  tray capacity enhancement, 14-32  
  tray considerations, 14-29  
  tray spacing, 14-29  
  truncated downcomers/forward push trays, 14-32  
  vapor and liquid-load definitions, 14-27
- tray columns, other hydraulic limits, 14-40  
  dumping, 14-46  
  entrainment, 14-40  
  froth emulsions, 14-48  
  loss under downcomer, 14-44  
  pressure drop, 14-42  
  transition between flow regimes, 14-47  
  turndown, 14-47  
  valve trays, 14-48  
  vapor channeling, 14-47  
  weeping, 14-44
- tray efficiencies, 14-48, 14-51, 14-52  
  calculation, 14-50  
    empirical efficiency production, 14-52  
    experience factors, 14-50  
    rigorous testing, 14-50  
    scale-up from a pilot or bench-scale column, 14-51  
    scale-up from an existing commercial column, 14-50  
    theoretical efficiency prediction, 14-53  
  definitions, 14-48  
  factors affecting, 14-49  
  fundamentals, 14-48
- tray towers and packed towers, comparison, 14-80  
  capacity and efficiency comparison, 14-81  
  factors favoring packings, 14-80  
  factors favoring trays, 14-80  
  trays vs random packings, 14-81  
  trays vs structured packings, 14-81
- tray-tower design, gas-liquid systems, 14-14  
  to 14-15  
  algebraic method for concentrated gases, 14-14  
  algebraic method for dilute gases, 14-14  
  graphical design procedure, 14-14  
  steam stripping, 14-15  
  stripping equations, 14-14  
  tray efficiencies in tray absorbers and strippers, 14-15
- trend alarm, 8-67
- trip valves, 8-91
- tube banks, 6-36 to 6-39  
  laminar region, 6-37 to 6-39  
  transition region, 6-37  
  turbulent flow, 6-36 to 6-37
- tubular reactor, 19-46  
  modeling, 19-9  
  tracers, 19-16
- tuning method:  
  known process models, 8-18  
  process model is unknown, 8-19
- turbidostat, 7-35
- turbine flowmeters, 8-65
- turbine inlet cooling:  
  background, 24-56  
  schematic, 24-57  
  technologies:  
    evaporative, 24-56  
    refrigeration, 24-56 to 24-57  
    temperature effects, 24-57  
  thermal energy storage (TES), 24-57  
  benefits, 24-57
- turbine meter, 8-60
- turbines, thermodynamics, 4-16
- turbulence, 6-46 to 6-47  
  closure models, 6-46 to 6-47  
  eddy spectrum, 6-47  
  time averaging, 6-46
- ultrafiltration:  
  applications, 20-50  
  component transport:  
    flux behavior, 20-52  
    solute flux, 20-53  
    solute passage/retention, 20-53  
  design considerations:  
    continuous, 20-54  
    single pass TFF, 20-54  
  economics, 20-53 to 20-54  
  membranes, 20-50  
  properties, 20-50  
  modules and systems, 20-50 to 20-51
- ultraviolet and visible radiation analyzer, 8-62
- under damped, dynamic measurements, 8-55
- uniform cycle, 8-19
- unit operations control, 8-39
- units, fluid cracking, 17-16
- units and quantities:  
  common, 1-17  
  SI:  
    base and supplementary, 1-2  
    derived, additional common, 1-2  
    derived, with special names, 1-2
- UOP cyclesorb process, 16-59
- UOP sorbex process, 16-56
- upper specification limit, 8-38
- uranium, leaching and extraction, 18-18
- vacuum, 8-52
- vacuum systems, 10-58  
  diffusion pump, 10-58  
  vacuum equipment, 10-58  
  vacuum levels attainable with various types of equipment, 10-60
- value, quick opening, 8-83
- value-improving practices, 9-48, 9-52
- valve assemblies, 8-85
- valve control devices, 8-84
- valve design, 8-79  
  materials ratings, 8-79  
  sizing, 8-79
- valve positioner, 8-84
- valve types, 8-74
- valves for on/off applications, 8-78
- vapor pressure, 2-477 to 2-478, 8-80, 12-4, 12-26
- liquids:  
  Antoine equation, 2-477  
  calculation methods, 2-477  
  Reidel equation, 2-477  
  Wagner vapor pressure equation, 2-477
- pure substances:  
  inorganic and organic liquids, 2-55 to 2-60  
  inorganic compounds, up to 1 atm, 2-65 to 2-79  
  water ice from 0 to -40°C, 2-48  
  water, liquid from 0 to 100°C, 2-48  
  water, supercooled liquid from 0 to -40°C, 2-48
- solids:  
  calculation methods, 2-478  
  Clausius-Clapeyron equation, 2-478
- solutions:  
  acetic acid aqueous solutions, total vapor pressures, 2-89  
  HCl over aqueous HCl solutions, partial pressures, 2-80  
  HI over aqueous HI solutions at 25°C, partial pressures, 2-89
- vapor pressure, solutions (*Cont.*):  
  HNO<sub>3</sub> and water over aqueous HNO<sub>3</sub> solutions, partial pressures, 2-88  
  NH<sub>3</sub> over aqueous NH<sub>3</sub> solutions, partial pressures, 2-92  
  NH<sub>3</sub> over aqueous NH<sub>3</sub> solutions, total vapor pressure, 2-93  
  sulfur trioxide over aqueous sulfuric acid solutions, partial pressures, 2-84 to 2-85  
  sulfuric acid over aqueous sulfuric acid solutions, partial pressures, 2-86  
  sulfuric acid over aqueous sulfuric acid solutions, total pressure, 2-87  
  water and CH<sub>3</sub>OH over aqueous methyl alcohol solutions, partial pressures, 2-94  
  water and HBr over aqueous HBr solutions at 20 to 55°C, partial pressures, 2-89  
  water in saturated air over aqueous H<sub>3</sub>PO<sub>4</sub> solutions, weights, 2-81  
  water over aqueous HCl solutions, partial pressures, 2-81  
  water over aqueous H<sub>3</sub>PO<sub>4</sub> solutions, partial pressures, 2-81  
  water over aqueous NaOH solutions, partial pressures, 2-94  
  water over aqueous NH<sub>3</sub> solutions, mole percentages, 2-91  
  water over aqueous NH<sub>3</sub> solutions, partial pressures, 2-90  
  water over aqueous sodium carbonate solutions, partial pressures, 2-94  
  water over aqueous SO<sub>2</sub> solutions, partial pressures, 2-81  
  water over aqueous sulfuric acid solutions, partial pressures, 2-82 to 2-83  
  water-sulfuric acid-nitric acid, vapor pressures of the system, 2-89
- vaporization/implosion transitions, 8-82
- vapor/liquid equilibrium:  
  calculations:  
    K-values, VLE, and flash, 4-31 to 4-32  
    data reduction, 4-30 to 4-31  
    definition, 4-28  
    equation-of-state approach, 4-32 to 4-34  
    extrapolation of data with temperature, 4-34 to 4-35  
    gamma/phi approach, 4-28  
    modified Raoult's law, 4-28 to 4-29  
    results for methanol/acetone, 4-35  
    solute/solvent systems, 4-31  
    thermodynamics, 4-35  
  variance-covariance matrix, 7-37  
  various liquids, surface tension, 2-309, 2-419  
  velocity; abnormal distribution, 10-20  
    minimum Hodgson numbers, 10-21  
    order of reliability for square-edged orifices and venturi tubes, 10-20  
    swirling flow, 10-20  
  velocity ratio versus Reynolds number, 10-13  
  resistive thermal detectors (RTDs), 10-7  
  static, 10-7  
  thermocouples, 10-7
- vena contracta condition, valve design, 8-80
- vena contracta region, valve design, 8-82
- venture-scrubber models, 17-37, 17-40 to 17-41
- venturi meter, 8-59
- vessels, agitated, jackets and coils, 18-25
- vibrofluidization, 17-6
- view factors, 5-20 to 5-24
- viscosity, 2-504 to 2-509  
  density, and kinematic viscosity of water and air in terms of temperature, 10-6  
  gases, 2-504  
    calculation methods, 2-505  
    Jossi-Stiel-Thodos method, 2-505

- viscosity, gases (*Cont.*):  
 Reichenberg group contribution values, 2-505  
 Reichenberg method, 2-505  
 Yoon-Thodos method, 2-505
- kinematic, 10-7
- liquids, 2-506  
 calculation methods, 2-506  
 Hsu method, 2-506  
 Hsu method group contributions, 2-507 to 2-508
- liquid mixtures, 2-506  
 calculation methods, 2-506  
 Grunberg-Nissan equation, 2-506  
 UNIFAC-VISCO method, 2-508  
 UNIFAC-VISCO group interaction parameters, 2-509
- viscous materials, mixing (pastes and doughs):  
 anchor, 18-28  
 double, triple shaft, 18-31  
 helical ribbon, 18-28  
 kneading, double arm, 18-31  
 planetary, 18-30
- VOCs, removal for air, costs, 22-51
- voidage, total, 16-10
- volumetric growth rate, 7-18
- volumetric humidity, 12-4, 12-5
- von Deemter equation, 16-44
- vortex shedding, 6-41 to 6-42  
 flowmeters, 8-60
- waste fuel analysis, 24-7
- wastewater, categories, 22-59
- wastewater, characteristics and treatment, 22-69  
 dissolved solids, 22-62  
 equalization, 22-63  
 grease and oil removal, 22-64  
 inorganics, 22-62  
 neutralization, 22-63  
 nutrients and eutrophication, 22-62  
 oil and grease, 22-63  
 organics, 22-60  
 pH and alkalinity, 22-62  
 physical-chemical treatment, 22-76  
 adsorption, 22-76  
 advanced oxidation process, 22-77
- wastewater, characteristics and treatment,  
 physical-chemical treatment (*Cont.*):  
 chemical oxidation, 22-77  
 concentration: thickening and flotation, 22-79  
 industrial reuse, 22-78  
 ion exchange, 22-77  
 membrane bioreactors (MBRs), 22-78  
 membrane processes, 22-78  
 objectives, 22-78  
 sludge processing, 22-78, 22-80  
 stabilization, 22-79  
 stripping, 22-77  
 pretreatment, 22-63
- primary, treatment, 22-64  
 chemical precipitation, 22-65  
 gravity sedimentation, 22-64  
 grit chambers, 22-64  
 screens, 22-64
- priority pollutants, 22-60
- secondary treatment, 22-65  
 activated sludge, 22-69  
 biological fluidized beds, 22-75  
 design of biological treatment systems, 22-66  
 determination of kinetic and stoichiometric pseudo constants, 22-68  
 fixed-film reactor systems, 22-74  
 lagoons, 22-72  
 packed-bed fixed-film systems, 22-74  
 reactor concepts, 22-67  
 rotating biological contactors (RBCs), 22-74  
 trickling filters, 22-3
- solids, 22-62  
 temperature, 22-62
- toxic substances, 22-64
- wastewater treatment, 22-63
- whole effluent toxicity (WET), 22-63
- water:  
 Antoine vapor pressure, 13-14  
 BIP data, 13-13  
 residue curve, 13-90  
 residue maps, 13-70, 13-79  
 saturated solid/vapor, thermodynamic properties, 2-412  
 sensitivity of composition and temperature, 13-79 to 13-80
- water (*Cont.*):  
 thermodynamic properties, 2-413 to 2-415  
 VLE data, 13-9, 13-7, 13-9  
 water content of air, 2-95  
 water substance along the melting line, thermodynamic properties, 2-416  
 water treatment ion exchange cycles, 16-54  
 wave shape, 16-38  
 weighting factor, 8-30  
 weights and measures, U.S. customary, 1-18  
 western electric rule, 8-37  
 wet basis, 12-26  
 humidity, 12-4  
 wet density, 16-10  
 wet-bulb temperature, 12-5, 12-6  
 wet-dry cooling, 12-25  
 wetted-wall columns, 14-82  
 flooding in wetted-wall columns, 14-85  
 mass transfer, 14-83
- Wien equation, 5-16
- wood, 24-7
- work:  
 ideal, 4-38 to 4-39  
 lost, 4-39
- working capital, 9-6, 9-9, 9-10, 9-17
- workstations, process control, 8-70
- Wurster coaters, sizes and capacities, 21-133
- xenon, 2-307, 2-417 to 2-418
- z transform, 7-30, 8-8
- zeolites, 16-8
- Ziegler and Nichols closed-loop method, 8-19
- zone melting, 20-5 to 20-6  
 applications, 20-6  
 component separation, 20-5  
 zone method, 5-24 to 5-27, 5-36 to 5-39  
 electrical network analog, 5-27 to 5-28  
 examples, 5-28 to 5-29  
 matrix formulation, 5-25, 5-36 to 5-37  
 methodology, 5-25  
 multizone enclosures, 5-27  
 two zone enclosure, 5-26
